

This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

- + *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.
- + *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.
- + *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.
- + *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at <http://books.google.com/>

A TREATISE ON
DIAGNOSTIC METHODS
OF EXAMINATION

BY

PROF. DR. HERMANN SAHLI

DIRECTOR OF THE MEDICAL CLINIC, UNIVERSITY OF BERN

EDITED, WITH ADDITIONS, BY

NATHANIEL BOWDITCH POTTER, M. D.

ASSISTANT PROFESSOR OF CLINICAL MEDICINE AT COLUMBIA UNIVERSITY (COLLEGE OF
PHYSICIANS AND SURGEONS), NEW YORK; VISITING PHYSICIAN TO THE
NEW YORK CITY HOSPITAL, TO THE FRENCH HOSPITAL, AND
TO THE HOSPITAL FOR RUPTURED AND CRIPPLED

Second Edition, Revised

*Authorized Translation from the Fifth
Revised and Enlarged German Edition*

EDITOR'S PREFACE

THE first edition of the English translation of Prof. Sahli's renowned book has met with a popularity scarcely equaled by that of the various German editions. It, therefore, seems unnecessary to comment at length upon the appearance of the second edition, which is as accurate and idiomatic a translation of the fifth German edition as I have been able to make.

The mistakes that crept into the first translation have been corrected and further editorial comments have been added. Several new diagrams and cuts have been inserted. The extensive alterations and complete revision of this latest German edition have, however, precluded the necessity for presenting to the English-speaking medical world more than the subject matter offered by the distinguished Swiss clinician.

Dr. C. G. L. Wolf, Professor of Chemistry in Cornell University Medical School, has edited the purely chemical portions of the text, and Dr. E. G. Zabriskie, Adjunct Professor of Neurology at the Post-graduate Medical School, has similarly edited the neurological section. Their editorial notes are designated by their initials. For their valuable assistance, and especially for that of my assistant, Dr. Wilson G. Wood, I wish to express my sincere appreciation.

NATH'L BOWDITCH POTTER.

NEW YORK, *January*, 1911.

PREFACE TO THE FIFTH EDITION

AFTER the fourth edition became exhausted there were so many demands for the book that the first half (on physical diagnosis) was revised and published first. The rest of the fifth edition is now completed. The many alterations and additions delayed its appearance longer than desirable, but this may be excused because of the great amount of work necessarily connected with revision. As in earlier editions I have aimed to pay equal attention to all departments of internal medicine, for any specialization, aside from those departments which must be separate on account of their special surgical technic, is, in my opinion, unwarranted and injurious to the consistent and symmetric training of the physician.

The chief changes in the first half, which appeared last year, concern the following points:

The chapter upon icterus has been rewritten, emphasizing Géraudel's investigations, which have opened up new avenues of thought in the pathology of this condition. The section upon edema has also been thoroughly revised in the light of the studies of Meltzer and Starling. An entirely new section has been introduced upon the determination of the cutaneous electric resistance, a subject which is of special diagnostic importance in exophthalmic goiter. The section upon our conception of the nature of fever and the principles involved in its estimation has been rewritten, and has been made to harmonize with my clinical teachings in reference to the general pathology of fever. These I have been unable to publish in detail, owing to lack of time. A brief section upon the teleology of the various forms of dyspnea has also been introduced. This explains the accurate adaptation of the dyspnea to the particular respiratory obstruction to be overcome. It should counteract the objections made by those who have recently taken such delight in criticizing any teleologic observation. The section upon the graphic records of types of respiration in disease is also new, and is based chiefly upon Hofbauer's investigations.

The chapter upon hemodynamics has been completely rewritten. In the study of the condition of the arterial wall mention has been made of Bäumlér's works, which have done much to restrict the erroneous diagnosis of general arteriosclerosis. In the sections upon tachycardia and bradycardia the so-called pseudotachycardia and pseudobradycardia have also been described. Under palpation of the pulse the use of varying degrees of pressure (dynamic palpation) to determine the strength of the pulse has been advised,—an attempt to rehabilitate a conception which has most unjustly become obsolete in modern medicine. In the new section upon my sphygmobolometer the subject of sphygmobolometry has been placed upon an accurate physical foundation, and, to my mind, the quality of the pulse has been made to furnish additional information of theoretic and practical diagnostic importance. The chapter upon sphygmography has been enlarged by a description of a number of procedures, including the method of taking simultaneous records. The following instruments have been described—the new Jaquet cardiosphygmograph and a simplified form of the same instrument, Mackenzie's polygraph, Runne's new sphygmograph holder, and an appliance of my own to utilize Jaquet's sphygmograph as a small clinical kymographion for vertical writing. In the section upon the interpretation of sphygmograms the negative sphygmograms described by Mackenzie as a source of error have been considered, and the section on the influence of respiration upon the sphygmogram has been partly rewritten and illustrated by new curves. A new chapter describes the employment of simultaneous records of the pulses of different arteries in the diagnosis of aortic aneurysms, and of narrowing of the principal arteries at their origin from the aorta. The modern analysis of the irregular pulse, included in the appendix of the last edition, has been incorporated in the text of the present volume. The discussion of this subject has been enlarged in many respects, and particular reference has been paid to Mackenzie's recently published studies. It has also been differently subdivided and illustrated with many new figures, most of them from Mackenzie, to whom I wish

to express my sincere thanks for permission to use his tracings. It has also been necessary to change radically the section upon sphygmomanometry, because many new facts have been added to our knowledge of this subject since the appearance of the last edition. A new section discusses the frequently misunderstood significance of the arterial maximum pressure, another the absolute sphygmogram, or the separate determination of the maximum and minimum pressure, the so-called pulse pressure, and the blood-pressure quotient. Further additions comprise the brief sections upon the measurement of the venous and of the capillary pressures. The chapter upon the venous pulse has been subjected to a thorough revision. The ventricular venous pulse, resulting from auricular paralysis and without tricuspid insufficiency (Mackenzie), and the transition forms between ventricular and auricular venous pulses have been described. The latter, though little noted in the literature, occur frequently. The tendency to lay too much stress upon every little wave of the venous pulse has been criticized.

In the chapter upon percussion a special section has been devoted to Selling's and R. Geigel's recent investigations upon the theory of the percussion note. In the explanations of dullness, particularly deep dullness, I felt it incumbent upon me to go somewhat deeply into details, since it seems that considerable confusion is apt to result here from misconceptions of physical laws. The effects of this confusion are experienced in practice, since unwarranted attempts are made to discredit methods of percussion which seem to me sufficiently well founded. I must, consequently, take up my position in reference to the more recent modifications of the method of percussion. ("Schwellenwert" percussion, orthopercussion, etc.) In the description of the topographic percussion of the lungs and of the heart, Moritz's and Dietlen's orthodiagraphic investigations have been mentioned, and although praiseworthy, they have been considered purely as anatomic studies in the living. I do not agree with these authors that this method will influence or modify in any way the results of percussion which have been accepted for years. In the description of pleuritic dullness I endeavored to interpret correctly Raue's paravertebral triangle of dullness, as well as the recently resurrected Garland's or Damoiseau's outline of dullness in pleurisy. In the discussion of mediastinal dullness mention has been made of that due to fat and described by von Hampeln. To assist in the early diagnosis of tuberculosis a section has been introduced upon the demonstration by percussion of a diminished respiratory expansibility of partially infiltrated portions of the lung. The theory of cog-wheel respiration has also been revised.

In the chapter upon auscultation a section has been devoted to the graphic recording of the cardiac sounds and to the chronoscopic determination of the length of the systole. This determination is based upon the employment of a new pocket chronoscope, constructed by Hipp, in Neuchâtel, according to my specifications. With this instrument, described here for the first time, hundredths of a second may be directly read.

The section upon the cardiac impulse gives a detailed description of the diagnosis of cardiothoracic adhesions. It introduces the subject of cardiolysis, and is based particularly upon Brauer's investigations. In view of the new graphic instruments described in this edition, the technic of cardiography has been more minutely set forth than heretofore.

In the chapter upon palpation the importance of the Trendelenburg position is emphasized. In reference to appendicitis an attempt has been made, upon the basis of Nothnagel's and Meltzer's investigations, to throw some light upon the nature of the colic. Unfortunately, this could not be done as fully as I could wish, in view of the practical importance of the subject. The decadence of this portion of diagnosis, as a result of superfluous surgical operations, furnishes a sad and highly culpable tendency of the twentieth century.

The section upon the compensation of cardiac diseases notes some new principles and points of view in reference to the explanation of hypertrophies and dilatations.

In the second half of the completed work the revision and amplification have been extensive. Only the most important innovations can be mentioned here.

In the section on the examination of the stomach the diagnostic value of the more recent statements, in regard to the size and position of the stomach obtained by orthodiagraphy, has been estimated. The desmoid test, suggested by the author, has been discussed more minutely. For, in spite of all the objections in the literature, this method has proved valuable in my clinic, providing in the given case the point at issue be rightly taken. The objections are based on a misunderstanding of what the method can and will do. I have recently adopted F. A. Hoffmann's method for estimating the ion-concentration of the gastric juice by the determina-

tion of the rapidity of the decomposition of methyl acetate by its free hydrochloric acid. I have added to the methods of pepsin determination mentioned in the last edition those of Volhard, Jakoby, Fuld, and Gross, as well as the refraction method worked out in my clinic by G. Schorer. Grützner's almost forgotten carmine method, simple and elegant enough to be permanent, has been more fully credited. In regard to the clinical use of the pepsin determination methods, some of the present procedures for the absolute pepsin determination have been established as anomalous points of view. Blum's, Fuld's, and Volhard's recent methods for estimating lab-ferment are fully described, as well as Salomon's test for the early diagnosis of gastric carcinoma. Sufficient suggestions for the bacteriologic testing of the gastric contents have been added, and the value of the dry and bouillon test meals, first described by me, has been discussed. It is hoped that the use of a small butyrometer adapted to the ordinary clinical centrifuge, and the resulting simplification of butyrometry of the gastric contents, will finally answer the unwarranted objections to this procedure. I have shown that the stomach can be completely emptied without lavage by a little-known method (employing a tube with several fenestra and a low position of the cardia), which I have long used and which has been published four years. This, among other things, has been responsible for discrediting Matthieu's procedure for determining the residue, to which many just objections have been raised, and which has been quite discarded in favor of the butyrometric method. I have often emphasized this in the debates over the gruel; but the writers, who believe that a method of gastric examination of more than twenty years' standing cannot be bettered, continue their futile opposition. It is hoped that the collected statements in this book will prove sufficient to convince the opponents of this method of its superiority. For them chiefly is meant the section on the criticism of the method. A new section on the demonstration of the most important poisons in the gastric contents is introduced.

The chapter on examination of the intestines has been much enlarged. Modern rectoscopy has led to such great advance in the early diagnosis of high rectal carcinoma that it should be as completely mastered by the average physician as laryngoscopy. It has been discussed at length. The wrong judgment of the value of the gluitoid test, so frequently mentioned in the literature, has been properly set forth. Schmidt's nucleus test, and the extraction of intestinal juice suggested by Volhard-Boldireff, are discussed. In the sections on intestinal parasites, the new species described in the literature have been included, *e. g.*, *Ascaris mystax*, *Schistosoma japonicum*, the many recently described, rare forms of *Tenia* and *Bothriocephalus cordatus*, and the occurrence in the intestinal contents of moth and fly larvæ (*Myasis intestinalis*) has been mentioned. The question of the use of test-nourishment, in the examination of the feces for determining the intestinal functions, has been critically discussed in a manner differing from the present practice. The technic of Schmidt's and Strassburger's fermentation test has been described. The section on the bacteriology of the intestinal contents is enlarged, and more recent methods for detecting blood in the feces are presented.

Numerous additions and improvements have been made to the section on urine examination; thus, in the appendix the Lambotte separator and my new simplified model have been described. The use of these improved instruments renders ureteral catheterization superfluous in the majority of cases. Physiologic and functional albuminuria have been discussed at length. The methods for differentiating serum albumin and globulin and the determination of F. A. Hoffmann's albumin quotient, as well as new methods for quantitative determination of albumin, such as the refractometer method of Schorer, Dénigé's titration and diaphanometric method, and the estimation of the albumin content by means of Tanret's reagent have been described. The so-called Bence-Jones albumosuria and the detection of the Bence-Jones proteid, as well as the vexed question of those urinary proteids which are precipitated by acetic acid in the cold (mucin, nucleo-albumin, euglobulin, Mörrer's albumin compound and nucleo-histon), are exactly described. New tests for blood in the urine, Ehrlich's paradimethylamidobenzaldehyde reaction for urobilinogen, Malfatt's milk-sugar reaction, Cammidge's reaction, and Lange's acetone reaction have been included. Tests for new substances have been included in the section on the detection of drugs and poisons in the urine. New methods for the quantitative estimation of sugar have been described, especially my useful modification of Pavy's method, the Gerard-Williamson titration method, and Wagner's exact fermentation saccharometer. All the more recent methods for determining urea, uric acid, and purin bodies known to me have been included, as well as Strauss's method for the quantitative estimation of indican, and the Folin-Gottlieb quantitative kreatinin determination. At the request of my French

colleagues, Bourget's phosphatometer has been described, and, in this connection, the nature of phosphaturia has been discussed as in the last edition. Sections on the quantitative estimation of ammonia, acetone, and oxybutyric acid have been made more complete by the addition of new methods.

The section on the bacteriologic examination of the sputum has been revised. I may merely mention here the discussion of the non-acid fast form of tubercle bacillus, the so-called tubercle bacillus fragments, the researches of Ellerman and Erlandsen on the improvement of methods of sedimenting for the demonstration of tubercle bacilli, the description and discussion of Bordet's whooping-cough bacillus, and the differentiation between streptococci and pneumococci and the virulent and non-virulent forms of streptococci.

The revision of the chapter upon the blood has perhaps been the most thorough of all. A complete exposition is made of the new methods for estimating the mass of the blood. In the discussion of the reaction of the blood, mention is made of Hamburger's alkali titration method, especially of the titration of the diffusible alkalies, as well as Friedental-Schultz's estimation of ion-concentration. New methods are presented in the sections on the coagulability of the blood and on hemoglobin estimation. Here, also, are suggestions concerning my hemometer, especially as to its standardization, in regard to which mistaken views are widespread, in spite of the complete directions for use given with the instrument. In this section conception of masked chlorosis has been introduced. The chapter on counting the blood-platelets has been altered. Hagen's hematimeter and Bürker's counting chamber have been described. A section on the practically important question of counting the blood-platelets at a distance from the bedside has been inserted. The original form of hematocrit was justly discredited. It has been rehabilitated here on account of improved and correct methods. The section on testing the resistance of the red cells to hypo-osmotic or other injury has been altered, and here the methods of Hamburger and Ribierre and their interesting results, especially in different forms of icterus, are discussed. Giemsa's, Leishman's, the panoptictriacid, and Ehrlich-Lazarus iodine-eosin methods of blood staining have been completely described. The Cabot-Schleip ring forms are described. The behavior of the blood in infectious diseases (leukocytosis, leukopenia, eosinophilia, lymphocytosis) is much more exhaustively discussed than before, and those diseases in which the blood findings have recently become known are mentioned (small-pox, measles, typhus, relapsing fever, dengue, Malta fever, rabies, tetanus, actinomycosis, syphilis, trichinosis, etc.). Ziegler's, Schindler's, and Arneith's studies on the qualitative changes of the leukocyte blood-picture in infectious diseases are discussed, as well as Neisser's researches on lipemia. The more recent investigations on trypanosomes, spirochetæ, piroplasmata, and warm embryos are discussed and explained by illustrations. The primary blood diseases are much more fully treated than formerly, and the very voluminous literature and my own experience are both made use of. O. Nägeli's excellent work on blood diseases and blood diagnosis was found especially valuable in this connection, and from it, with his permission, the plates of the myeloblasts described by him were reproduced. In the section on pernicious anemia I have advanced the theory that this disease is a consequence of diminished hydrochloric acid in the gastric juice and the resulting diminution in the absorption of iron. I have mentioned this in my clinic for years, but this is the first time I have published it. The section on lymphomatosis is altered. More recent observations on the blood in Banti's disease, multiple myeloma, purpura, scorbutus, Barlow's disease, hemophilia, myxedema, Basedow's disease, malignant tumors, paroxysmal hemoglobinuria, lead and phosphorous poisoning, icterus, asthma, and burns have been presented. The new methods for the estimation of the viscosity of the blood have been included, as well as those for the quantitative estimation of serum albumin, the detection of potassium cyanide and prussic acid, the quantitative estimation of uric acid, the oxydase reaction, and the examination of the blood for bile-pigment and urobilin. The agglutination reactions of the blood have been revised, and the examinations of the bactericidal power of the blood and the Wassermann-Neisser-Bruck serum reaction in syphilis have been included. This chapter has been enriched by two excellent color plates.

The sections on the examination of the alimentary canal have been exhaustively revised. I would mention particularly the detailed discussion of the examination of the esophagus by the Röntgen rays, and of esophagoscopy, in which Brünings' new broncho-esophagoscope is described. The special findings in each affection of the esophagus are exhaustively described, and Neisser's sound palpation of tuberculous bronchial glands also referred to. The chapter also contains a description of two recently devised sounds—a diverticulum sound and a dilatation sound.

I have included in the chapter upon rhinoscopy a number of cuts of rhinoscopic findings in empyema of the accessory sinuses which are of great practical importance.

The section upon exploratory punctures is considerably enlarged. Here special attention is directed to the more detailed presentation of cytology of the puncture fluids, to the discussion of the existence of proteolytic ferment action of the exudates, to the elaboration of pressure determination in pleural exudates, and to a chapter on exploratory cranial puncture, introduced especially by Neisser and Pollack.

The sections on examination of the nervous system also contain many additions, all of which cannot be mentioned here. For example, testing of the sensory effect of faradic vibrations and of muscle contraction (Curschmann); discussion of Rauteenberg's discovery of the alternating contractility of muscles under electric stimulation, as well as of myaotony, also described by Brautenberg; and of some remarks on condenser discharges. The psychogalvanic reflex phenomena, described by Veraguth, is briefly alluded to.

The section on aphasia has been thoroughly revised, and the isolated alexias and agraphias more exhaustively considered than in the earlier edition. P. Marie's conception of aphasia is criticized adversely, and its consideration furnishes the opportunity of introducing a conception of logasthenia. Several new diagrams cast fresh light on aphasia. Localization has been amplified by the introduction of a series of new cuts. In all the chapters dealing with the examination of the nervous system I have endeavored to explain the pathologic symptoms by physiologic facts, *e. g.*, in showing at length the connection between the stasis of nervous excitation and physiologic chorea, physiologic trembling, etc. The more recently described "Phenomena," reflexes, etc., are given as faithfully as possible, in so far as they have come to my knowledge.

Finally, it need hardly be remarked that, besides the more important changes and additions which are mentioned above, and which are partly comprised in new chapters (compare the systematic index), numerous details, both of form and style, have been altered, and considerable new material, based on my own observations, and hitherto unpublished, has been added.

Owing to all these additions, the book is enlarged by about 300 pages, the number of cuts increased from 291 to 389, and the number of plates from 5 to 7. The work would have been still larger, and exceeded one volume, were it not condensed by omitting many of the older and more or less disputed methods. Experience teaches us, however, that there are false as well as true advances in medicine, and that, in our rapidly moving age, the established good is sometimes forsaken for short-lived theories. I would, therefore, recommend the possessors of earlier editions to keep them, since they contain many useful methods which will again come into good repute. I think it necessary to emphasize this point, although I have taken great pains in the critical selection of material, and have tried to present what I personally have found to be of the greatest value at the present time.

One word more in regard to my attitude upon the Röntgen ray diagnosis. The invaluable early enlightenment which we owe to this method is given full credit throughout the new edition. Compare, in particular, the chapter on percussion of the heart; on the position of the stomach and the examination of the alimentary canal. On the other hand, I am still opposed to including the Röntgen technic in a book of this character. I have selected chiefly methods the technic of which I have personally mastered, and such as can be expected to be within the grasp of any trained physician of the present day. The Röntgen technic itself does not come under this head. It is true, I frequently make use of Röntgen ray examination in my clinic, but the technic is managed by a specially provided Röntgen ray expert. I do not consider myself qualified, therefore, to instruct others in this technic. A mere compilation of Röntgen technic, which naturally I could review only superficially, does not enter the scope of this book, as it is intended chiefly to describe my own methods of work.

The arrangement in my clinic alluded to above is in conformity with the fact that, despite a progressively increasing demand for the rounded education of physicians, it can scarcely be expected that every practitioner should be a master of the Röntgen technic. Nor is this a disadvantage. Examination with the Röntgen ray plays in internal medicine, as in my clinic, the part of a referee in difficult questions, but is not to be resorted to at first, and not in all cases, but only when other methods of examination are unsatisfactory; and, according to my opinion, this is the position it should continue to occupy. According to this, instruction in the Röntgen technic should remain the province of special courses and special textbooks. I contend that it is no sign of progress when the Röntgen method super-

sedes to too great an extent the other methods of examination in a medical clinic and exceeds its function as a court of final appeal.

In the first place, the Röntgen ray examination is not adapted to many, and especially the commonest problems which the older methods readily solve, and, hence, often leads to errors. In the second place, the necessity of a cumbersome apparatus militates against its ever becoming a principal factor in medical examination. Such a special method of examination should not, for didactic reasons, be placed in the foreground of the clinic, lest the students get quite a false impression of medicine, and become accustomed to consider Röntgen ray examination as a refuge for the lazy, which would make the tedious training in physical diagnosis superfluous. I have frequently been confronted with the lamentable diagnostic inefficiency of those physicians in whose studies the Röntgen ray examination was placed on a high pedestal, and who consequently had not thoroughly mastered the art of percussion. These unfortunate persons remind me of certain candidates who, in an examination on tuberculous meningitis, knew nothing except that it could be diagnosed by lumbar puncture and the demonstration of tubercle bacilli in the cerebrospinal fluid. What could such a physician do in practice! If, in clinical instruction, we exaggerate the importance of Röntgen ray examination, we offer the student a stone for bread. For what can a practitioner do with it if he have a small practice in the country or in a mountain village? And yet we must train physicians for this type of practice and turn out skilful educated practitioners. So, in this case, sense may become nonsense, and a benefit, a nuisance.

I cannot close without reiterating that this book is not a mere compilation, and that the major portion of its contents is derived from my own experience, and represents personal views and observations hitherto unpublished, which have not been sent as original contributions to the journals because my time has been insufficient, and because I am not in favor of too much medical scribbling and of manufactured articles. I mention this because the present work scarcely deserves to be quoted from. This is explained by the fact—and it is to the detriment of an harmonious progress in medicine—that medical literature of the present day is almost exclusively sent to journals. Besides, it is usually taken for granted that text-books, not to include the systems of medicine which are so popular to-day, and which display so many names on the title page, are merely compilations and contain nothing new. If an author has anything important and new it is assumed that he would have first marketed it among journals. My own views are quite at variance with this opinion. The following instance, among others, justifies my remarks. In the *Deutsche medizinische Wochenschrift* for 1904, p. 716, a prominent author, discussing certain mistakes in auscultating the lungs, asserted that this book was the only one of the current text-books to include a brief chapter upon the subject, "evidently based on a paper read by Treupel at the Society of Freiburg physicians." If he had taken the trouble to inform himself, he would have discovered that this chapter was almost exactly the same, even in its first edition, 1894, i. e., four years before the appearance of the paper from which the data were supposed to have been gathered.

HERMANN SAHLI.

INTRODUCTION

HISTORY AND OBJECTIVE EXAMINATION

THE first essential for correct diagnosis in any given illness is a careful account of the subjective and objective symptoms and of their manner of development. These statements, made by the patient or his relatives, are called the *history*. It may be divided into two parts: first, the history in the narrow sense of the term, including the patient's story of his illness up to the time the physician sees him; and, second, his account of his present symptoms, an account which must always be supplemented by an objective examination. The answers to the questions obtained in the history frequently furnish sufficient evidence to make a comparatively accurate diagnosis without examining the patient. Countless examples might be mentioned in illustration; for instance: A patient says that a few days before, when in apparently good health, he was suddenly seized with a severe chill and a stabbing pain in his side, and that ever since then he has been feverish and short of breath, coughing and expectorating rusty sputum. With such a story a physician would naturally make the diagnosis of croupous pneumonia.

Before attempting any objective examination, and merely by skilfully directing his questions, an experienced physician can obtain a fair idea of the disease, even in cases where the evidence is less conclusive than in the above example, although an exact diagnosis can usually be made only after completing the objective examination; for many diseases furnish only subjective symptoms. There are even cases in which the history affords the only clue to diagnosis. A ripe experience is requisite in order properly to utilize the history in making a diagnosis. A complete knowledge of the pictures of all the diseases which might enter into consideration in any given case is very essential in selecting the proper questions, as well as a keen critical power in interpreting the value of the evidence given in the history, since otherwise unessential facts might be made conclusive points in a diagnosis. Only years of experience can overcome one very constant difficulty—the varying individuality of patients. An hysterical society woman describes to her physician symptoms which, in a sturdy laborer, would be properly attributed to pathologic changes; but the adept practitioner understands that such complaints are nothing more than the expression of the peculiar, sensitive, and exaggerating mental condition of an hysteric person, and so does not lay too much stress upon their significance. Vice versâ, a stolid, callous peasant often complains very little even when afflicted with a serious disease; or, again, a patient normally sensitive may be so benumbed by a disease that he does not complain at all. In the latter instance the great contrast between the subjective well-being (euphoria) and the objective visible disease frequently suggests a very unfavorable prognosis.

Without depreciating the value of the statements of the patients and their friends, it is evident from what we have said that the methods of objective examination, with which this book is concerned, contain the most essential elements in diagnosis. Although we have illustrated the possibility and the occasional necessity of making a diagnosis merely from the history, yet we could as easily mention innumerable instances where the most skilled practitioner could not form an approximate conception of the disease without the most searching physical examination. Even in the simplest of cases no physician should neglect the precaution of examining his patient carefully, including in such an examination all the organs. For, on the one hand, some organic diseases do not excite subjective symptoms; and, on the other hand, there may be some organic changes which annoy the patient sufficiently to lead him to consult his physician, while others of the greatest importance may exist of which he has no suspicion, and which the objective examination first discloses.

Objective examination includes a number of different methods, some depending on mere observation, but others requiring especial technical, chemical, or physical aids. The beginner must very early acquire facility in all these methods of examination. Their mastery will furnish the groundwork for acquiring extended experience in clinical observation upon the symptomatology, the course, and the prognosis of disease, and for obtaining reliable data for therapy.

A FEW SUGGESTIONS FOR TAKING HISTORIES

It is very difficult to give any detailed directions which will be generally effective in taking a history. In serious diseases only an able and experienced physician is capable of performing this task thoroughly, and he will need to utilize his entire medical training. Since we shall mention in the appendix upon special diagnosis most of the methods made use of in history-taking, in the following paragraphs we need only give a few rules to serve as a framework for the beginner to broaden and build upon as his knowledge and experience grow.

Few persons are so mentally constituted as to communicate to the physician simply and directly the medically important facts of their ailments. Most patients relate a mass of unimportant matter and say nothing about the essentials, and only skillfully planned questions will prevent the patient or his relatives from irrelevancy. But a patient should never feel that he is being guided, nor that his physician does not enter with interest and sympathy into all the minute details of his trouble. Putting a mild curb upon the patient's volubility does not mean that one should concern one's self exclusively with the typical and characteristic symptoms of disease; because many things apparently immaterial in the eyes of the beginner, who knows a disease only as a scheme, have really considerable interest and a great importance. Even many conditions which have apparently nothing at all to do with the medical aspect of the case—for example, occupation, family affairs, etc.—are very helpful in comprehending the clinical picture, especially the etiology and, with it, the treatment. In short, the patient should be led to relate neither too much nor too little.

It is quite as important that the physician himself should be accurate in framing his questions. It is easy enough to ask too little, but difficult to ask too much or to question too minutely, not only on account of the multiplicity of the appearances of disease to be mastered, but even more on account of the danger of considering any important point as proved after a few hasty questions. In the author's opinion this is the most frequent and serious fault which the beginner perpetrates; *e. g.*, a feverish patient is asked if he has had a chill, because such a symptom would suggest a definite disease, pneumonia. Without much thought most patients answer this question in the affirmative; but more careful questioning develops the fact that the supposed chill is in reality only the slight chilly feelings accompanying nearly all feverish diseases. In the typical chill of pneumonia the patient's teeth chatter, and he shakes as if immersed in ice-water. This is quite a different symptom

in its diagnostic significance from the slight shivering of fever. The patient's statement that he has had a chill is not sufficient; we must inquire more particularly as to the nature of the chill. Often enough patients betray their mistake by using the word chill in the plural. Similar errors may arise from the statements patients make in regard to many other symptoms and long-standing diseases. The names they give to their former illnesses are especially apt to be incorrect and often occasion serious errors, for many are diagnoses made by the laity and many others are incorrect; *e. g.*, most cases of so-called "meningitis" which have been cured. Again, patients with tuberculosis often misname an acute exacerbation of their disease as "influenza"; further, so-called "catarrh of the stomach" is usually a manifestation of the general effect of tuberculosis. "Rheumatism" is another diagnosis which must always be looked upon a little skeptically. Frequently enough the clinical picture shows that the so-called "rheumatism" is a manifestation of tuberculosis or of pleurisy, etc. Similarly, many other names of diseases, such as "nervous fever," "joint rheumatism," "dysentery," if accepted without criticism and without minute interrogation, may lead to errors in diagnosis. The best way to avoid such mistakes is to disregard names given by the patient and to make one's own diagnosis by establishing as objectively and accurately as possible the symptoms of the preceding disease.

A further and equally serious fault is the tendency of many beginners to start from a preconceived notion of the diagnosis and to extract from the patient all possible facts in the history which will coincide with this supposed disease. To recognize this fault should be sufficient to avoid it effectually.

We can hardly ask too detailed questions as to the *influences of heredity*, inquiring accurately concerning parents, brothers, sisters, children, uncles, and aunts. An inquiry as to whether this or that disease has occurred in the patient's family will usually elicit a negative reply. To determine the facts accurately the disease in question must be quite specifically designated, possibly even a summary of the symptoms detailed. A patient may deny the occurrence of pulmonary disease in his family; but should we ask if either parent had a chronic cough, had expectorated blood, or lost a good deal of weight, we can frequently enough become convinced that one or the other suffered from tuberculosis.

In regard to neuropathic taint, we must question very accurately and particularly. For example, an epileptic will practically always deny the occurrence of any nervous disease in his family. We may, however, obtain a positive reply by asking whether his father, mother, brother, sister, uncle, or aunt was epileptic, if they had suffered from nervous attacks, or if they had been nervous or mentally affected in some other way.

If the histories be difficult to obtain or if patients contradict themselves, it is advisable to repeat questions later on, thus frequently clearing up some complicated point. The repetition of our task with stupid and prattling patients, unfortunately, obtains for us little more than renewed contradictions. Even this is a relative gain, for at least we discover how little we can trust them, and draw no false conclusions.

In general, good history-taking requires much diplomacy, tact, and knowledge of people and of medicine. A physician should never allow a patient to feel that he is in a hurry. The public considers that the physician has time for everything and everybody. Sit quietly, even if you are sitting upon hot coals, and wait for a favorable moment to interrupt, in a diplomatic way, the flow of talk. An excellent medical precept is not to fatigue a patient seriously ill with too thorough questioning, but to obtain as much as possible from the relatives, or to leave parts of the history until a later period. Furthermore, it is always advisable to discuss with the patient alone facts which he might wish to conceal from others. Finally, the beginner puts only a small part of the necessary questions, not realizing how much must be asked in order to make a complete history. Few rules can be given, but the following table will probably be of considerable service:

Scheme for History-taking

Date; personal statements (name, age, position, occupation, residence); condition, *i. e.*, married or not; complaint; onset of the present illness; a description of the symptoms in the order of their appearance.

Etiology.—More exact information about the occupation and mode of life, injuries, strains, taking cold, errors in diet, etc. Infectious diseases in the neighborhood. Previous treatment and course of disease.

Past History.—Any antecedent disease like the present. If so, course of same. Injuries. Other preceding illnesses; infectious diseases; and of these especially:

joint rheumatism, scarlet fever, measles, whooping-cough, typhoid fever, erysipelas, malaria, sore throat, gonorrhea, syphilis. Previous symptoms of disease: Edema; dyspnea; cough; expectoration; expectoration of blood; palpitation of heart; difficulties of urination and alterations in the urine; constipation; diarrhea; icterus; vomiting; vomiting of blood; abnormalities of hunger and thirst; headache; marked changes of weight. In the female sex: chlorosis; pregnancies; births; menstruation; gynecologic difficulties. All these symptoms and conclusions which the past history furnishes must be analyzed in the same way as the symptoms of the present disease. (See below, 2. Complaint.)

Heredity.

THE GENERAL ROUTINE OF AN OBJECTIVE EXAMINATION

The following plan the author considers an excellent method for a routine examination, the order of the questions being the natural and practical one. The individual observer may expand the scheme in accordance with the contents of the work in question.

1. *Expression of countenance and general deportment of the patient; voice; speech; psychic behavior.*

2. *Complaint.* (See Scheme for History-taking.¹) *Kind of sick feeling. Weakness. Loss of flesh. Disturbances associated with the nervous system. Disturbances in connection with the organs of respiration.*

Dyspnea, constant or paroxysmal. The exciting cause of the paroxysms. Breathing slow or rapid during attack of dyspnea. Stridor, inspiratory or expiratory.

Cough, with or without expectoration. Characteristics of the expectoration. Admixture of blood. Peculiarities of the latter. Subjective sensation respecting the source of the expectoration (throat, larynx, nose).

Pain with breathing. Its location.

Disturbances in Connection with the Circulation.—Palpitation, constant or paroxysmal. Apparent exciting cause of the paroxysm (agitation, exertion, or posture). Palpitation accompanied by sensation of pain (left arm, back, epigastrium, precordia). Palpitation accompanied by dyspnea. Subjective sensation of arrhythmia (*i. e.*, tripping or skipping of the heart-beat). Edema. Amount of urine.

Disturbances of the Digestion.—Appetite. Pain. Influence of the ingestion of food and drink upon the pain (favorable or unfavorable). Time of onset of pain (soon after eating, during the night, in a fasting condition). More exact location and radiation of pain (back, right shoulder). Nausea. Vomiting. Amount and character of the vomitus (mucus, blood, food). Its taste (sour, bitter). Time of vomiting, pointing to retention or not. Belching (sour, bitter, rancid). Evidence of hemorrhoids. Constipation: Frequency of bowel movements. Character of feces: color. Large scybala, abnormally small lumps. Distention of abdomen and other discomforts when constipated. Flatulence. Diarrhea: frequency, consistence, color, amount of each defecation. Pain in defecation. Tenesmus. Bloody or slimy evacuations.

Disturbances of the Urinary Apparatus.—Urgency. Bladder or kidney pain. Radiation of the pain. Tenesmus of bladder. Amount of urine. Pollakiuria. Conspicuous qualitative changes of the urine (cloudy, bloody, smoky). Passing of stone, gravel, or sand. Phenomena of retention or incontinence. (See Examination of Bladder.)

Other Disturbances.—Fever. Night-sweats. Headache. Thirst. Insomnia, and its apparent cause.

3. *History proper*, in conformity with the above plan.

4. *Examination proper*, which should cover the following points:

Build, development, and nutrition.

Temperature, frequency of pulse and of respiration.

Characteristics of Skin.—Turgidity, color (pallor, cyanosis, icterus); eruptions; pigmentation; scaling; striæ; final confirmation of other external diseases (joint affections, erysipelas, etc.).

Head and Neck.—Mucous membranes, especially conjunctivæ, tongue, gums, pharynx, tonsils, herpes labialis, glands, goiter. Cervical veins (their dilatation or pulsation).

Respiratory Apparatus.—Dyspnea: its character; polygopnea, oligopnea, in-

¹ Similar rules apply as in taking the actual history (see above). Moreover, it is of great importance to ask directly about the symptoms enumerated here because patients themselves are so apt to think them of the least importance.

spiratory or expiratory dyspnea, stridor, shape of thorax, type of breathing, breathing excursions, diaphragm phenomenon, retraction of thorax, topographic and comparative percussion and auscultation of the lungs, fremitus.

Circulatory Apparatus.—Inspection and palpation of the precordia. Visible and palpable pulsation over that area. Location of apex-beat. Thrills. Percussion and auscultation of the heart. Exact examination of the arterial pulse. Rapidity, rhythm, fullness, strength, tension, resistance of artery wall, conformity of the frequency of the radial pulse with that of the cardiac pulsation, comparison of the pulses of different arteries. Exact examination of the venous pulse. Auscultation of the arteries. Liver pulse. Capillary pulse.

Digestive Apparatus.—Inspection and palpation of the abdomen; its shape and fullness; visible and audible peristalsis; sensitiveness to pressure, palpable tumors, resistance, peritoneal friction. Palpation and percussion of the stomach, intestines, liver, gall-bladder, spleen, and peritoneum. Inspection of the vomitus and of the feces.

Urinary Apparatus.—Manner of urination; palpation of the kidneys and bladder; percussion of bladder. Catheterization. Character of urine; amount; color; cloudiness; specific gravity; testing for albumin, sugar, and other abnormal constituents.

Special Examinations which may be Necessary or Even the Most Important of all in a Given Case.—Examination of the nervous system in accordance with the plan to be mentioned later. Rhino-, laryngo-, ophtho-, otoscopic examination. Testing the blood, including counting the corpuscles, estimating the hemoglobin, and the microscopic examination of the fresh and stained blood. Microscopic examination of the sputum, of the urine, of the vomitus, and of the feces. Bacteriologic examinations. Sphygmography, sphygmomanometry, and sphygmobolometry. Examination of the esophagus. Examination of the stomach by means of the stomach-tube (distending with gas, a test-meal, the determination of the motor power of the stomach by distention with water). The desmoid and glutoid reactions. The examination for pyloric stenosis by means of cork capsules. Distention of the colon to determine the location of tumors. Examination of the rectum. Of the male and female genitalia. Exploratory punctures.

It is the province of special pathology or of special diagnosis to interpret the signs of disease discovered in this manner, to correlate, and to unify them into a definitely conceived disease of etiologic, functional, or anatomic nature.

GENERAL CONDITION OF THE PATIENT

POSTURE IN BED

The general deportment of the patient is the first thing which attracts our attention and influences our judgment as to his condition. In many cases even the patient's relatives will reveal whether the illness is serious or slight. Ordinarily, physicians see seriously sick patients in bed, while those with slight ailments walk about. Yet there are countless exceptions. Sometimes seriously ill patients go to bed only as the last extremity; and, as is well-known, patients may walk about even during the height of typhoid fever or pneumonia. Vice versâ, many patients take to their beds on account of very slight ills. These peculiarities depend upon the social position and the employment of a patient, and upon the great difference in the individual susceptibility to sickness. Besides, we must remember that even very slight ailments which always run a favorable course are sometimes associated with such distressing symptoms that the patient is compelled to take to his bed. Despite such exceptions, we may say that certain diseases necessitate rest in bed, others are ambulatory. Patients with the acute exanthemata are commonly found in bed by the physician because they feel very ill. The same is true of circulatory disturbances, peritonitis,

meningitis, pneumonia, and acute inflammatory rheumatism. It is ordinarily easy enough to determine whether the patient keeps his bed on account of feeling ill, weak, and perhaps feverish, on or account of dyspnea, pain, or other difficulties, which are increased by walking about.

THE EXPRESSION

The expression is of great diagnostic importance, enabling the skilled physician to draw conclusions as to the subjective feelings and the mental condition of the patient. The terms commonly applied to the expression—suffering, anxious, painful, careworn, uneasy, very ill, agitated, dulled, stupid, flustered—are perfectly plain without further explanation. Feverish patients present a characteristic appearance; sometimes they have a peculiar animated look, at other times an exceptional depression of the mimic faculty, often combined with glistening eyes, a feverish redness, and an increased turgidity of the skin of the face. The facial expression of a patient suffering from dyspnea is quite as distinctive, it being dependent upon peculiarities in the appearance of the skin (cyanosis, edema) and upon the mimic elements. The dilatation of the nares (see later), combined with the open mouth, is especially characteristic. (See p. 50 for a description of the typical *facies Hippocratica*.) The unusual expression of tetanus, called the *risus sardonicus* (sardonic laugh),¹ has been variously described. While the mouth is distorted as in laughing, the upper part of the face, especially the brow, is wrinkled, just as in the expression of trouble or sorrow. Tetanus poison apparently contracts the muscles of the entire facial territory and causes a combined stimulation of practically antagonistic muscles.

MENTAL CONDITION

A patient's facial expression and his demeanor during our questioning furnish the best means of estimating his mental condition.

ACTIVE AND PASSIVE POSTURE IN BED

A critical observer obtains diagnostic points by noticing the position which the patient assumes in bed. The less the general feelings are affected, the more natural and unconstrained is his pose. He tosses about, pushes the pillows straight, and shifts his attitude when one position has become uncomfortable. This is called an active position in bed (active dorsal or lateral posture). On the contrary, very weak, helpless, or unconscious patients appear very different. Their attitude is lax, essentially controlled by the laws of gravity. Should such a patient slide down against the footboard, he would remain lying there, for he is incapable of drawing himself up, even if the position be very uncomfortable and his breathing embarrassed. This is called a passive position in bed (passive dorsal or lateral posture).

CONSTRAINED ATTITUDES

Some very characteristic postures are almost diagnostic of certain diseases. For example: respiratory, cardiac, or renal affections associated with much dyspnea prevent a patient from lying upon his back: in

¹ This name is derived from "sardone," a poisonous plant of the ancients, the ingestion of which produced such an expression.

the first place, because the accessory muscles of respiration can be used to advantage only in the sitting posture, with the spine fixed and sometimes the arms; in the second place, because, if fluid has accumulated in the abdominal cavity, the sitting posture partially relieves the diaphragm of its pressure;¹ and finally, because the influence of gravity possibly relieves the venous congestion of the brain and of the respiratory center in particular. With extreme dyspnea, the so-called "*orthopnea*," a patient cannot lie down, but, exhausted, is obliged to sit erect, bracing himself with his elbows and forearms upon the arms of his chair in an endeavor to utilize the accessory muscles of respiration and, if fluid be present in the abdomen, to avoid pressure of the anterior surface of the thighs upon the distended abdomen. It is worth remembering that the accumulation of a considerable quantity of blood in the veins of the lower extremities may afford some relief to the lungs and the heart, so that elastic bandages around the legs, temporarily shutting off a con-

Fig. 1.—Case of cerebrospinal meningitis. Photograph taken from above; patient lying asleep. Marked retraction of neck, flexion of thighs and legs (Harlem Hospital, Dr. R. G. Wiener).

siderable amount of venous blood, may enable the patient to lie down, even though for a very short time.

Constrained lateral positions are very suggestive, for they almost always depend upon unilateral affections of the thoracic viscera. If, on account of pulmonary consolidation or of compression by a pleural effusion, the function of one lung be abolished, the patient usually lies upon the affected side, in order to afford the sound lung the freest possible expansion. Should there be much pain, such a position is generally reversed, because the weight of the body increases the pain; but sometimes when the pain depends practically upon the breathing the patient will lie upon the affected side, and so limit the respiratory excursion by partially fixing the painful side with the body weight. In heart disease,

¹ Except, of course, when an enormously distended abdomen is crowded by the thighs in the sitting posture.

and sometimes in health, one side is more comfortable than the other to lie on. The position which dislocates the heart, the great vessels, and the mediastinum most, thereby rendering the breathing difficult, will be avoided. Lying on one side will sometimes relieve a patient who is perpetually tormented with a cough when in the dorsal decubitus. As one can easily imagine, with constantly renewed secretion in pulmonary cavities certain positions will aggravate a cough if the secretions are being continually poured out upon the healthy bronchial mucous membranes. In some positions the cavity would become entirely

Fig. 2.—Adiposity: The enormous accumulation of fat over and within the abdomen simulates a collection of ascitic fluid.

filled before any overflow would excite the paroxysm of coughing. The latter then completely empties the cavity, thus affording the patient a temporary rest. The diagnosis of a cavity would be strongly suggested by such a history.

With colic, with cardialgia, and sometimes with intestinal obstruction patients generally prefer to lie upon the abdomen, because the tension of the distended intestines is diminished or their position shifted and the pain relieved; but in peritonitis the abdomen is so sensitive to pressure that the dorsal decubitus is assumed. On account of the epigastric tenderness, it is comparatively rare to find a patient with a gas-

tric ulcer lying upon the abdomen, unless such a position frees the ulcer from the contact or pressure of the gastric contents, *e. g.*, if situated upon the posterior wall. Patients with headache sometimes prefer to lie upon the abdomen. The characteristic positions of patients suffering from cerebrospinal meningitis or wry-neck depend upon cramp-like contractions of certain groups of muscles; some peculiar paralytic positions, upon paralyzes of muscles.

GAIT AND ATTITUDE

An alert, erect attitude and a rapid walk usually signify good physical condition, while a stooping, relaxed posture with a slow, fatigued gait indicates that the person is seriously ill or mentally depressed. (For a description of various gaits characteristic of definite nervous diseases see Examination of the Nervous System.)

DEVELOPMENT AND STATE OF NUTRITION

A robust, vigorous, or muscular physique means that the bodily dimensions are rather above the normal, whereas a weakly or puny physique would indicate the contrary. The subcutaneous fatty layer (*panniculus adiposus*) is perhaps of even more importance than the muscles in estimating the state of nourishment. The former varies within normal limits in accordance with the age, sex, and occupation of patients. Corpulence is generally associated with a weak musculature. Nursing infants possess an extremely well-developed layer of fat; during child-

Fig. 3.—Pronounced emaciation in a chronic disease. Case of multiple myeloma (New York City Hospital).

hood it gradually diminishes, and in the third or fourth decade increases again, while at old age it finally diminishes. A marked tendency to corpulence is often observed in women, especially after the menopause.

Most chronic diseases are accompanied by a noticeable deterioration of the general nutrition. This is due either to lack of appetite, and, hence, insufficient food, or to defective assimilation, or to excessive combustion of the food assimilated. Emaciation is particularly evident in chronic febrile and digestive diseases, and becomes most pronounced in severe and prolonged typhoid fever, in phthisis, in carcinoma, especially esophageal carcinoma, and in certain cases of diabetes mellitus. In these diseases the musculature suffers a loss almost as rapidly as the fatty tissue. Marked emaciation nearly always suggests chronicity.

From a diagnostic standpoint van Noorden believes that lack of exercise incident to such patients' symptoms is more responsible for fat accumulation than any inherent deficiency of their oxidizing powers. Typical examples are the pronounced panniculus adiposus usually observed in chlorosis and in pernicious anemia. These diseases are not accompanied by emaciation unless the digestion is decidedly affected and food ingestion consequently limited or some other complications are present. The appearance of an anemic patient emaciated from gastric carcinoma is, therefore, strikingly different from that of a case of pernicious anemia—a point of the greatest importance in the frequently difficult differential diagnosis of these two conditions.

BODY WEIGHT

Observation of weight over a certain length of time furnishes an excellent guide to the state of nutrition. Minute cautions in regard to

A

B

[Fig. 4, A —Free diuresis in a nephritic with marked anasarca and fluid in both pleural cavities, selected from the editor's service at the New York City Hospital. The patient excreted about 72 pints of urine and lost 58 pounds.]

Fig. 4, B.—An ominous increase in the weight of a patient with mitral and tricuspid lesions and a pulsating liver, selected from the editor's service at the New York City Hospital. This patient was walking about the ward when compensation failed; he was ordered to bed on January 25, and with rest, purgation, and cardiac tonics he began to lose weight and compensation was promptly established. Each square represents 16 ounces of fluid or 1 pound of weight.—Ed.]

the accuracy of the scales, weight of different clothes, etc., are hardly necessary to enumerate. Unless accurately estimated, the weight is of no value. It is more accurate to weigh the body always either before or after eating, since a hearty meal will often make a difference of one or more pounds. General edema or the accumulation of fluid in one of the large serous sacs will considerably increase a patient's weight, while free catharsis, diuresis, or diaphoresis will rapidly diminish it. Daily weighing in these cases furnishes very good evidence of the progress of the disease.

Infants should be weighed daily or weekly, to keep track of their nutrition. The normal weight of the newborn is (females) 3000 gm. (6 lbs.) to (males) 3500 gm. (7 lbs.) (Uffelmann). During the first three or four days of life there is a physiologic loss of 200 to 300 gm. ($\frac{1}{2}$ lb.). Gerhardt¹ cites the following table:

Daily increase in 1st month 25 gm.					Daily increase in 7th month 15 gm.				
"	"	2d	"	23 "	"	"	8th	"	13 "
"	"	3d	"	22 "	"	"	9th	"	12 "
"	"	4th	"	20 "	"	"	10th	"	10 "
"	"	5th	"	18 "	"	"	11th	"	8 "
"	"	6th	"	17 "	"	"	12th	"	6 "

Quetelet's² table [from which the following has been constructed.—Ed.] does not take into account the weight of the clothes, which has been estimated to be in men about $\frac{1}{8}$ and in women about $\frac{1}{4}$ of the total weight, although, of course, such figures must vary considerably.

Year.	Male.				Female.			
	Weight.		Height.		Weight.		Height.

¹ Gerhardt, Lehrbuch der Kinderkrankheiten, 1881, p. 2.

² Anthropométrie, 1870.

As a mnemonic aid, Quetelet gives us the rule that the healthy male adult should weigh as many kilos as his height in centimeters exceeds one meter. The female's normal weight is somewhat greater. During childhood this rule does not apply.

In the author's opinion such rules are quite arbitrary since the relationship varies both with the race and with the individual. This he emphasizes because he is convinced that such rules easily become dogmas and thus cause the layman as well as the physician to indulge in a rigid dietetic régime to bring the body-weight into accord with the accepted standard. Such a course only too frequently results in injury to a previously healthy individual.

MENSURATION

An individual's general development must be judged by a comparison between his age, weight, and height. [The following tables, based on the so-called "Nylie Graphic Table," are useful. They are correct to one pound.—Ed.]

Circumference of the Chest.—The chest measurement furnishes a very good idea of the state of development. It is used in many countries in examining army recruits. Frölich¹ recommends the following method: The measuring tape is to be applied horizontally at the level of the nipples in front and just beneath the angles of the scapulae behind while the arms are held horizontally. The measurements during extreme inspiration and again during extreme expiration are to be recorded, the difference representing the *chest expansion*. He found among recruits that the average in men of twenty years was for expiration 82 cm. (32½ in.), for inspiration 89 cm. (35½ in.), and the chest expansion 7 cm. (2½ in.), and he attaches considerable diagnostic importance to these figures, because he noted that in emphysema, in pulmonary consolidation, and pleural effusions the circumference, especially during expiration, was increased, while the chest expansion was diminished, and this diminution might persist for some time after

the disease had subsided. The chest expansion is diminished (the so-called Bryson's sign) if the cartilages become ossified. This is often the case in exophthalmic goiter.

CONFIGURATION OF THE THORAX

NORMAL SHAPE OF THE CHEST

A normal chest, such as one sees so beautifully illustrated in the masterpieces of classic statuary, should be symmetric, the surface well rounded, without sharp corners or depressions; the intercostal spaces only visible between the lower ribs; the subcostal angle about 90° ; the sternum nearly straight in profile, without a decided angle between the gladiolus and the manubrium; and the sternovertebral somewhat shorter than the transverse diameter. The gradual increase in the horizontal diameters of the thorax should form a sort of pyramid, with its base below, but the graduation should not be too marked, and the shoulder girdle, or in females the breast, should offset this difference. The shoulders should be nearly horizontal, the scapulæ lying flat against the back, clavicles not too prominent, and the supra- and infrascapular fossæ not too deep.

PATHOLOGIC SHAPES

Emphysematous Chests.—These abnormal forms depend upon an emphysematous enlargement of the lungs, and they possess one feature in common—the thorax seems abnormally widened and prominent. The sagittal diameter is generally increased and the subcostal angle more obtuse than in the normal thorax. When the emphysema is diffused over the entire lung or when mostly limited to the lower chest, the thorax looks as if in a normal position of deep inspiration; but when caused by forced expiration (coughing), the emphysema is situated more in the upper chest, because the respiratory power acts more upon the lower parts of the thorax. Then the upper thoracic aperture appears enlarged and the so-called "barrel chest" is produced. These are the two different types.

Fig. 5.—Emphysematous chest
(Dr. W. H. Smith, Massachusetts
General Hospital).

The Paralytic Thorax.—Contrasted with the emphysematous thorax, the so-called *paralytic thorax* is abnormally flat,¹ long, and sometimes narrow; the ribs, both in front and behind, have a marked downward direction; the intercostal spaces are widened; the subcostal angle

¹[Woods Hutchinson, Niles, and others do not believe that the tuberculous chest is abnormally flat. The former (Jour. Amer. Med. Assoc., 1897, xxix, p. 512; *ibid.*, 1903, xl, p. 1196) measured 20 tuberculous chests and found them to be more nearly round than the average normal chest. The measurements were made on an imaginary horizontal plane passing through the junction of the fourth costal cartilages with the sternum. Dividing the anteroposterior by the transverse diameter gives the ratio (usually expressed as a percentage) which

is very acute; the supra- and infraclavicular fossæ are deep; the intercostal muscles and those of the shoulder girdle are slightly developed; and the shoulder-blades project noticeably, like wings, because of a weakness of the muscles, especially of the serratus magnus. This type of chest is observed in *weakly* or *cachectic* individuals, and very commonly

Fig. 6.—Paralytic chest (phthisis) (Dr. W. H. Smith, Massachusetts General Hospital).

Fig. 7.—Paralytic chest (phthisis) (Dr. W. H. Smith, Massachusetts General Hospital).

in *phthisis*. It was formerly considered a predisposing cause of consumption, and is now frequently spoken of as "the phthisic chest."

The reader may consult D. Rothschild's original articles¹ for his views upon the importance of the so-called sternal angle, the angle between the manubrium and the body of the sternum, in the development of the paralytic thorax.

the former bears to the latter, and is called the *clinical index* of the chest. From several thousand measurements made in the German Army and at the Yale gymnasium the average normal adult clinical index is estimated at 70 per cent.; 350 cases of tuberculosis collected from various observers showed an average index of 79.7 per cent. Niles² found in 1022 measurements of tuberculous patients (about half of which he made himself) that 720 of them (70 per cent.) showed an index above 72 per cent., 219 (21 per cent.) of them were within normal limits, *i. e.*, between 68 and 72 per cent., while only 83 (8 per cent.) were below 68 per cent.—ED.]

¹ Verhandl. d. Congresses f. innere Med., 1899, p. 590; and the monograph, *Der Sternalwinkel*, Frankfurt, J. Abt, 1900.

² *Ibid.*, 1909, lii, p. 1916.

Scoliotic, Kyphotic, and Scoliokyphotic Thoraces.—These terms are applied to twists and deformities of the chest which are observed as a sequence of spinal curvature. They are frequently quite pronounced. It is often difficult to detect such deformities from the front; but by noting the low stature, the short thorax, and the marked breadth of shoulders an experienced eye can generally discover them.

Rachitic Chests.—Rickets may be responsible for all sorts of chest deformities. Perhaps the most characteristic is the keel-shaped prominence of the sternum called *pectus carinatum* (pigeon-breast). It is associated with a shortening of the anterior diagonal horizontal diameter and an increase in the sternovertebral diameter of the chest (Figs. 8, 9).

Fig. 8.—Pigeon-breast (Dr. R. C. Cabot, Massachusetts General Hospital).

A transverse groove (Harrison's groove) often marks the insertion of the diaphragm to the ribs. The so-called "rachitic rosary," a beaded enlargement at the line of junction of the bony ribs with their costal cartilages, can be felt as well as seen. It generally disappears in later childhood. The other rachitic deformities may persist, or they may become modified to a greater or less extent.

Boat-shaped Chest of Syringomyelia.—Pierre Marie and Astié¹ described, under the name of "thorax en bateau," a depression of the upper portion of the anterior chest-wall, which, so far as we know, is only observed in syringomyelia. The cavity lies in the median

¹ Soc. méd. des hôpitaux, 1897, 19, ii.

line, as if sunk against the spinal column, and extends downward as far as the lower edge of the pectoralis major; it may be as deep as 5 cm. The atrophy of the pectorals and of the other muscles takes no part in producing this appearance.

Funnel-shaped Chest and Cobbler's Chest.—The true *funnel-shaped chest* is either congenital or else develops gradually and without any known cause. It consists of a funnel-shaped depression of the lower end of the sternum, which frequently reaches quite deeply into the interior of the chest. It may lead to circulatory or respiratory disturbances resembling those observed in kyphoscoliosis. **Cobbler's**

Fig. 9.—Rickets: Note the size and shape of head (see p. 37), the rosary, Harrison's groove, kyphosis, prominent belly, bowing of legs, and the enlargement of wrists (Dr. W. L. Stowell, Randall's Island Hospital).

may acquire a very similar deformity, due to the constant pressure against the lower end of the sternum. The cobbler type is, however, limited to the inferior portion of the sternum, or even to the xiphoid process alone.

Asymmetry of the Chest Due to Disease of the Thoracic or Abdominal Viscera.—An expansion or a contraction of one chest-half may result from various affections of the thoracic viscera, *e. g.*, a large pleural exudate, a pneumothorax, or even to a slight extent a croupous pneumonia. The alteration may be general over one entire side or localized. The affected side may be the larger or the smaller.

A considerable pleural effusion or a pneumothorax produces an enlargement of the affected side of the thorax, an obliteration of the intercostal spaces, a dislocation outward of the nipple and of the scapula, a convexity of the spine toward the affected side, and an elevation of that shoulder. The last two deformities, both probably due to an alteration of the center of gravity, make the patient look as if he were carrying a weight on the affected side.

The lower thorax may be enlarged by a decided increase in the size of the liver or spleen. Such an enlargement will become still more noticeable if tympanites or ascitic fluid distend the abdomen enough to prevent the dropping of the enlarged liver or spleen. An aortic aneurysm or an intrathoracic tumor may cause a localized enlargement of the thorax. This will be situated at the point of contact of the

Fig. 10.—Funnel-shaped chest (Dr. R. C. Cabot, Massachusetts General Hospital).

growth with the thoracic wall. Actual contact is not, however, necessary, because, even when the growth or aneurysm is merely in close proximity to the wall, a localized bulging will be caused by the diminution in the intrathoracic negative pressure, *e. g.*, an aortic aneurysm, even when covered by the lung, will cause a local prominence. Neither does a pleural effusion need to be under positive pressure, as is so commonly supposed, in order to enlarge the affected side of the chest. (See what is said regarding dislocation of organs by exudates, p. 87.) Cardiac enlargements and pericardial effusions give rise to a precordial bulging. The lower thorax will be quite uniformly and decidedly expanded by any marked increase in the contents of the abdomen, *e. g.*, meteorism, ascites, large ovarian tumors, or pancreatic cysts.

Chronic indurative processes in the lung, *e. g.*, chronic pneumonia with or without bronchiectasis, chronic tuberculosis, are apt to cause a

unilateral contraction of the thorax, sometimes including the entire half of the chest. The coincident pleuritic contraction may be partly responsible for the deformity. After the absorption of a pleuritic effusion it is very common to find a retraction of the affected side of the chest instead of the previous enlargement. This is due to the fact that the lung, incased in thick fibrous adhesions, has been compressed so long that it can never again expand fully, and that the pleuritic adhesions

Fig. 11 Scoliosis and asymmetry of the thorax: patient with fibroid phthisis of left lung; left chest smaller than right, left shoulder (affected side) higher than right; left scapula nearer the spine; dorsal spine concave to left; lumbar spine with a compensatory convexity to left (New York City Hospital).

tend to contract and draw the thorax in. These pulmonary and pleuritic conditions are, of course, very commonly combined. When the contraction of one side of the chest is very decided, the scapula, clavicle, and the neighboring soft parts are plainly depressed; the nipple and the shoulder then approach the median line, and the spinal column presents a curvature with a concavity toward the affected side. The corresponding dislocations of the thoracic viscera will be discussed under

Topographic Percussion. Noticeable increase in the depth of the supra- or infraclavicular fossæ suggests a retraction of the apices, and is, therefore, especially if unilateral, an early and important sign in pulmonary tuberculosis. [A localized prominence above the clavicle may be due to a cervical rib.¹ The tumor is usually situated one or two finger-breadths above the clavicle, is hard, more or less rounded, and generally immovable. There may be another upon the opposite side. Palpation may, and x-ray examination certainly will, distinguish this condition. For an account of the symptoms referable to the circulation and to the nervous system see the comprehensive article by Keen, which contains a complete bibliography. Thrombosis of the left subclavian and jugular veins in one of my patients at the City Hospital produced a localized supraclavicular tumor which simulated an enlarged lymph-node.—Ed.]

Inspection reveals these chest deformities more accurately than direct measuring with the tape; probably because the eye notes differences not only in the size of the chest, but in the extent of the respiratory excursions. The latter are, of course, always diminished on the affected side. The extent of the respiratory excursion is the surest way to decide whether a given deformity is due to an enlargement of one side or a contraction of the other side. Another reason why measuring with the tape is apt to be inaccurate in pleuritic effusions is this. The lower end of the sternum is generally dislocated to the affected side, so that the middle line of the sternum forms an acute angle with the true median line of the body. Therefore, measuring from the middle of the spinal column to the middle of the sternum is not accurate. We should measure to a plumb line dropped from the middle of the jugulum (*ligne du cordon*).

Willez's cyrtometer is a practical instrument for measuring and picturing chest deformities, and is rather better than the ordinary tape; but, as a matter of fact, a narrow lead band, about the thickness of a lead pencil, is more convenient than the specially devised instrument. It can be accurately applied to the chest-wall at any desired level and removed without altering its shape; a tracing can then be made upon paper and measurements taken. In those cases in which the lead band cannot be removed without changing its shape the outline of the thorax should be obtained by taking the segments separately and allowing them to overlap. Such tracings are sometimes very instructive in following the course of an obstinate pleurisy. (For the discussion of more complicated apparatus see references cited below ²)

Rothschild employs the so-called sternogoniometer for the measurement of the sternal angle.³

SIZE AND SHAPE OF THE HEAD

According to Strümpell, the horizontal circumference of the skull in the newborn is normally 40 cm., at the end of the first year 45 cm., and at puberty 50 cm.

During the first eight or nine months the large fontanel slightly increases in size; about the tenth month it begins to diminish, and at the sixteenth month it should be closed.

Hydrocephalus may be either congenital or acquired early in life. The skull is enlarged (up to 50 cm. in the first months of life), and most of the bones are separated by broad sutures and fontanel. The cranium looks like a big bladder, tapering downward. The orbital roofs are projected downward, causing the eyes to look downward in a very characteristic fashion; and the face is diminutive in comparison. The cranial bones are very thin, and when pressed upon crackle like parchment.

Rachitis is characterized by a peculiar malformation of the skull. Although the longitudinal and transverse diameters are approximately normal, the cranium has a distinctive appearance, due to the prominent frontal and parietal eminences and to the flattened and vertical position of the occipital bone, forming the *square-shaped head* (*tête carrée*). The large fontanel may remain patent into the third, fourth, or even the sixth year, and the sutures a correspondingly long time. The

thinned areas of bone over the cranium, and especially over the occipital bone, will furnish the same parchment crackling described above.¹

¹ Special Pathology must be consulted for a description of the deformities of the face in acromegaly and of the asymmetry in hemiatrophia facialis progressiva.

EXAMINATION OF THE SKIN

An examination of the skin should not be restricted to cutaneous diseases alone, because in diseases of the internal organs we meet with all manner of changes in the skin, which can be appreciated by the sense of sight or by that of touch.

COLOR OF THE SKIN

The normal fleshy tint of the skin is due to the color of the blood shining through the epidermis and the superficial layers of the cuticle. The color of the skin may be modified, both physiologically and pathologically, by (1) a quantitative increase or decrease in the amount of flesh color; (2) a qualitative change due to abnormal pigmentation. The first is better observed in the face; the second, in other parts of the body, where the normal flesh color is not so prominent. Many qualitative variations, occasioned by abnormal pigmentation, are, however, determined better over paler uncovered areas.

QUANTITATIVE CHANGES OF THE FLESH COLOR

The intensity of the flesh color depends upon—(1) the intensity of the blood color; (2) upon the amount of blood contained in the vessels; (3) upon the thickness of the layers of skin covering the vessels. Any one of these three factors may vary and so cause alterations in the flesh color of more or less diagnostic importance.

PALLOR

Pallor Depending Upon Oligochromemia.—A pale face presupposes anemia, or a diminution of the coloring power of the blood (oligochromemia)—that is to say, a qualitative alteration of the blood. For we do not recognize any real quantitative diminution ("blood poverty" of the Germans) except that which occurs after a profuse hemorrhage, and this is rapidly made up by reabsorption of lymph and water, thus causing again the condition of oligochromemia. As we shall see later on, pallor is a very uncertain guide in the diagnosis of oligochromemia.

Pallor without Oligochromemia.—It is impossible to diagnose anemia from pallor alone. A careful blood-examination (see Section on p. 765) is absolutely essential in order to avoid the mistake of diagnosing anemia in a patient with normal blood simply because his face is pale; or reassuring a patient with red cheeks whose hemoglobin percentage is only 50.

Aside from oligochromemia, the causes of pallor of the face are numerous, *e. g.*, many people absolutely well, without a symptom or sign of disease, are abnormally pale. The only way to explain such pallor, providing, of course, the conjunctival and mucous membranes are not so pale, is to assume either an abnormal opacity of the epidermis or a scanty supply of blood-vessels in the face. During the course of an illness a patient sometimes gradually becomes paler and paler, and although the hemoglobin percentage remains normal, the physician, unless he examines the blood, will certainly consider the condition

one of oligochromemia. Here we must suppose that the pallor is due either to a diminution of the total amount of blood, or that the skin contains less blood than normally as a result of morbid changes in the circulation. We are usually unable to determine clinically which of these two factors is responsible for the pallor, because we possess no simple, accurate, and practical method of determining the amount of blood in the living body, and because we know very little regarding the diminution of the quantity of blood in relation to the body weight except in cases of hemorrhage.¹ That altered circulatory conditions do occur in many cases of morbid pallor is made all the more probable by the existence of certain other symptoms,—weakness of the pulse, general bodily weakness, slight grade of cyanosis (see p. 40, et seq.), dilatation of the external cutaneous veins, nausea, dizziness,—such as are frequently observed from a diminished arterial blood-supply to the brain. It is difficult to determine whether the diminished amount of blood in the small arteries and capillaries, which is certainly the cause of the pallor, depends upon an alteration in the cardiac activity or in the capillary tonus. Pallor is associated with a low blood-pressure if entirely dependent upon diminished cardiac activity, the capillary tonus remaining constant; but if the small arteries dilate, pallor does not result. High blood-pressure is characterized by a marked pallor, provided there is a very decided capillary tonus.

A closer study of the connection between a normal hemoglobin percentage and this pallor would be of some service for careful treatment; because so long as every pale patient is considered anemic, as is, unfortunately, too often the case in practice, we shall not progress very far toward proper therapy. Affections of the stomach, heart disease, phthisis, and cachexias of all kinds, although associated with pallor, often show a normal blood. All such conditions may, of course, lead later on to oligochromemia.

The temporary pallor caused by nausea, collapse, or violent psychic impressions practically comes under the head of an alteration in circulation, being due partly to vasomotor influences but partly to cardiac weakness inducing lowered arterial pressure.

ABNORMAL REDNESS OF THE SKIN OF THE FACE

If the above conditions which produce pallor be reversed, an abnormal redness of the skin will result. A hemoglobin percentage as high as 120, although very rare, may be responsible for an increased color. The actual existence of such a condition as true plethora is uncertain because of the lack of any simple method for the determination of the quantity of the blood in the organism. Nevertheless, true plethora probably does exist, not only in the diseases recently described, as polycythemia, but also in such ruddy individuals as have always been designated by the laity as full-blooded. The grounds of probability furnished by v. Recklinghausen for the existence of true plethora in this latter group seem to have been thoroughly justified. In many cases such an appearance is caused by an abnormally thin or transparent skin; in

¹ Although it seems probable that extreme emaciation is associated with a diminution in the amount of blood, it has never been proved that this diminution is out of proportion to the loss of body weight. See also section upon "The Determination of the Quantity of the Blood."

others, by a local increase in the amount of blood sent to the face. The so-called "rosy chlorotics" are supposed to possess blood-vessels of abnormal transparency. In all such cases an examination of the blood is absolutely essential before a diagnosis of oligochromemia can be made. A suggestion is, however, often obtained by comparing the pallor of the conjunctivæ with the rosy hue of the cheeks.

People who spend most of the day out-of-doors, and especially those who are exposed to all sorts of weather, generally acquire a ruddy face from the constant increase of blood in the exposed portions.

Alcoholics are usually flushed on account of the dilating influence of alcohol upon the vessels. Minute dilated radicles may also be seen just underneath the epidermis, or an acne rosacea, which is so frequent in drinkers. As is well known, this same peculiarity is often observed in perfectly healthy individuals, in whom it is difficult to determine any cause. Fever produces a characteristic redness, ordinarily combined with some puffiness and moisture of the skin of the face. The lax condition of the muscular coat of the vessels is apparently responsible. This is evident in a sphygmographic tracing. The flush of fever is most noticeable in the cheeks, especially when contrasted with a pallor such as is observed in tuberculous patients (so-called hectic flush). Psychic excitement, shame, violent physical exertion, external applications of heat to the skin (baths, insolation), the inhalation of nitrite of amyl, or a moderate grade of atropin- or opium-poisoning, all cause a flushing of the face from vasomotor influences. The reddening in these cases may spread to the neck and to the upper part of the trunk. Poisoning with carbon monoxid ordinarily produces a very intense redness of the face, which is supposed to be due to an alteration of the blood. The latter, however, contains so little carbon monoxid that it is even difficult to determine it with the spectroscope, so that the explanation is unsatisfactory.

Hemicrania and some affections of the cervical sympathetic sometimes cause a unilateral redness of the face, which is commonly associated with a unilateral pupillary change. The redness of the face associated with various cutaneous diseases and the acute exanthemata need not be discussed.

CYANOSIS

By this term is meant a bluish tinge of the skin and mucous membranes which depends upon the poverty of the capillary blood in oxygen and its abnormal richness in carbon dioxid. The cutaneous capillaries may be either of normal or dilated caliber. In the former instance we have the so-called pale cyanosis; in the latter, the dark cyanosis. Since it is even a deeper blue than ordinary venous blood, we must assume in explanation some peculiarity in the skin-covering.

General Cyanosis.—A number of factors share in the production of general cyanosis:

(1) Insufficient oxidation of the blood in the lungs from any cause, so that the arterial blood in the capillaries is poor in oxygen and therefore dark.

(2) Cardiac obstruction to the venous return, so that the veins are dilated, the skin contains more venous blood than normally, the current is sluggish, and the blood is charged with more carbonic acid.

(3) Combination of (1) and (2).

(4) Vasomotor dilatation of the cutaneous capillaries (vasomotor paralysis), with a coincident disturbance of the general interchange of gases.

In (1) we have a pale, in (2) to (4) a more or less dark, cyanosis.

When due to cardiac obstruction, the most intense cyanosis is observed in the extremities because the circulatory difficulty increases with the distance from the heart; but the intensity of the cyanosis may also be affected locally by vasomotor influences. The face, especially the cheeks, lips, and ears, shows cyanosis very plainly because the color of the blood is more apparent in these situations even in health. The marked cyanosis which is sometimes observed in the nose and in the knees is to be attributed to vasomotor influences.

General cyanosis will therefore appear in any respiratory or circulatory affection. These two systems are so intimately related and so dependent one upon the other that if the cyanosis be very pronounced, we should naturally attribute it to an interference with both respiration and circulation, no matter which is primarily affected.

The following disturbances, primarily *respiratory*, cause cyanosis: Any affection preventing the free entrance of air to the lungs, *e. g.*, retropharyngeal abscess; croup; pseudocroup; edema or spasm of the glottis; paralysis of the inferior laryngeal nerve; tumor of the larynx; foreign bodies in the pharynx, larynx, trachea, or bronchi; any kind of tracheal stenosis, as by goiter or other tumors; strangulation; bronchitis; bronchial asthma, etc.

Affections which diminish the amount of breathing surface of the lungs, *e. g.*, emphysema; all varieties of pulmonary infiltration; atelectasis; compression of the lungs by an exudation or by pneumothorax. In this connection it is interesting to note that in pulmonary consumption the cyanosis does not reach so high a grade as the amount of breathing surface involved would lead us to expect. This is probably because the emaciated body contains less blood and needs less oxygen, so that what remains of the healthy lung tissue is practically sufficient to aerate the diminished amount of blood.

All affections which influence the activity of the respiratory muscles: paralyzes and atrophies of the muscles of respiration (bulbar paralysis, etc.), as well as spasms (tetanus, epilepsy); further, any affection causing pain enough to inhibit respiration.

In all these disturbances the arterialization of the blood in the lungs is primarily affected, and later on some venous congestion is apt to result because the circulation lacks the help of the pumping action of respiration.

The following disturbances, primarily *circulatory*, cause cyanosis from congestion:

Uncompensated cardiac affections; valvular lesions and affections of the heart muscle; arteriosclerotic, cardiac, and nephritic changes; strains upon the heart; pericarditis, etc., as well as paralysis of the vasomotors.

Mitral defects, both those of insufficiency and those of stenosis, even when compensated, cause a certain degree of cyanosis. This is respiratory in nature, and depends upon the increased pressure in the pulmonary circulation, upon the resulting rigidity and brown induration of the lungs, and upon the accompanying bronchial catarrh, all of which impede the respiration.

The cyanosis of *congenital heart disease* is often more pronounced than

in any other condition. It depends upon venous congestion, or upon the admixture of arterial with venous blood, or upon both. This admixture is not, however, the only cause of the often enormous cyanosis presented by these cases. (See section upon Congenital Heart Lesions.)

The cyanosis which is caused by *vasomotor paralysis* depends upon a dilatation of the small vessels (the arterioles, capillaries, and smallest veins). It differs from the other types of general cyanosis in a lack of distention of the larger veins, and in the peculiar grayish-blue color of the entire surface of the body, without the localization at certain points of predilection, which is so characteristic of the other forms. (See the following section.)

Certain poisons, notably antifebrin and nitrobenzol, turn the blood very dark by changing the hemoglobin into methemoglobin. This is not a true cyanosis, although the body surface is blue.

Cyanosis from Local Causes.—Localized areas of the skin may become cyanotic without any disturbance of the general circulatory or respiratory system. Either local venous congestion from compression or thrombosis of large or small veins, or else some vasomotor disturbance, will be found to be responsible. Examples of the latter variety are the cyanosis of the hands, feet, and ears produced by the local action of cold, the cyanosis of paralyzed extremities, of the hands and feet of hysteric individuals, and occasionally of perfectly healthy individuals. In many patients this local cyanosis is not infrequently combined with an edema of the affected part; and it has been claimed, although upon insufficient grounds, that such a combination has some connection with hysteria (*œdème bleu des hystériques*, see p. 55).

This purely vasomotor cyanosis evidently depends upon a degree of vascular dilatation sufficient to produce stagnation from inadequate *vis à tergo*. The process may be compared to a running stream which, from the lack of a definite river-bed, becomes a swamp. One might think that such a dilatation of the vascular system, by diminishing the resistance, would assist the current. In this case, however, the current would not flow uniformly over so wide a territory, but through the shortest channels the current is very rapid, whereas the parts at some distance from these direct channels contain blood which is almost stagnant. The bright-scarlet spots which the writer has frequently observed scattered through the blue of vasomotor cyanosis furnish a proof of the accuracy of this theory. They correspond to areas of increased capillary current.

A cyanosis of similar origin appears in certain inflammatory processes. When extreme it is, of course, an unfavorable sign.

Cyanosis of the skin is naturally associated with increased loss of heat, so that cyanotic parts generally feel cold.

ICTERIC COLORATION OF THE SKIN (JAUNDICE)

Icterus is the peculiar pathologic yellow discoloration of the skin and mucous membranes, caused by bile-pigment or some of its derivatives. The ordinary form (*obstructive icterus*) depends upon a total or a partial occlusion of the bile-duct, so that instead of being emptied into the intestine, some or all of the bile is absorbed and stains the various tissues, *e. g.*, the skin and the mucous membranes. This discoloration varies in tint from a pale lemon yellow to a dark brown, olive green, or almost black. The darker shades (*melasicterus*) always signify an obstruction of long duration. They are caused either by a great excess of pigment accumulated in the skin or by a transformation of the original bile-pigment to related darker pigments.

Icterus is usually first noticed in the conjunctiva of the sclera and upon the unexposed parts, which are covered with but a thin layer of epidermis and are only slightly pigmented. After the obstruction has persisted for a short time the skin of the face and the mucous membrane of the mouth share in the discoloration. Pressure of the finger, by diminishing the amount of blood, sometimes makes the yellow of a mild icterus plainer. Because the gums are normally so pale they show icterus before the rest of the mouth-lining. Unless very intense, jaundice cannot be appreciated by artificial light.

In looking for icterus we generally begin by examining the conjunctivæ. We should remember that the yellowish color of the subconjunctival fat, so pronounced in cachectic individuals and in drunkards, is sometimes mistaken for icterus. The distribution of this fat is largely limited to the neighborhood of the folds in the mucous membrane, so that a careful examination of the tightly drawn conjunctiva nearer the cornea generally prevents a mistake. *Pinguecula*, peculiar formations of colloid degenerated connective tissue which contain yellow pigment, are situated within the palpebral folds on either side of the cornea. They may be another source of confusion.

Certain races and some individuals exhibit a yellowish tint of skin, which a beginner might confuse with a faint jaundice; but a careful examination of the conjunctiva should prevent this mistake.

The yellowish discoloration in picric-acid poisoning can be easily differentiated from icterus by the history, etc., as well as by the urinary examination.

Bile-pigment occurs in the urine and sweat of icteric individuals. Yellowish stains upon the linen sometimes attract a patient's attention before he has observed the yellow color of his skin. The saliva is, for the most part, unaffected. The feces become pale and more or less clay-colored on account of the lack of bile. The absorption of certain biliary salts with the biliary pigment produces, at least in fresh cases, a slowing of the pulse and considerable itching of the skin.

Although obstructive jaundice arises most frequently from a catarrh of the biliary passages, it may depend upon serious changes in the liver itself, *e. g.*, cirrhosis, carcinoma, abscess.

Another type of jaundice which differs from the obstructive by the fact that the feces are unaffected (*i. e.*, of normal color) depends upon very imperfectly understood causes.

Icterus neonatorum belongs to this type. The old idea was that the drying up of the blood-current in the umbilical vein after birth caused a sufficient lowering of the pressure in the portal vein to enable the bile-pigment to pass from the liver into the portal vein. Quincke¹ and Schreiber² defend Peter Frank's theory of the cause of jaundice in the newborn. Frank argued that the bilirubin absorbed from the meconium, instead of being stored up in the liver for further use, escapes directly into the general circulation by way of the ductus venosus Arantii. This duct generally remains open for a short time after birth. One argument in favor of this theory is the fact that icterus neonatorum occurs most frequently in premature infants.

The cause of the jaundice which is not infrequently observed in infectious diseases (pneumonia, pyemia, and yellow fever) is not perfectly clear; it probably depends upon the absorption of bile-pigment from the liver. It has been claimed that a catarrh of the biliary passages, due to the general venous congestion, is responsible for the jaundice in pneumonia, but microscopic examinations of the liver tissues in such cases have shown that the bile-ducts were normal. Stagnation and reabsorption of bile from the lack of the usual rhythmic pressure exerted by the diaphragm upon the liver has been cited as another explanation of the icterus in pneumonia. If jaundice occurred only with pneumonia which involved the lower right lobe, this theory might seem more plausible. Experience in acute yellow atrophy of the liver has shown that under some circumstances a parenchymatous degeneration of the liver without any biliary obstruction may be the cause of a

¹ Arch. f. exp. Path., vol. xix, p. 34 et seq. ² Berlin. klin. Woch., 1895, No. 25.

reabsorption icterus, so that it does not seem impossible that a similar process, of which more will be said later, may be the cause of the icterus in pneumonia, pyemia, and yellow fever. Liebermeister created an expression to embody this idea in the term "acatectic" icterus (*κατέκτις*, to hold back) or *diffusion icterus*.

The term *hematogenous icterus* was formerly applied to all these cases of obscure jaundice as well as to that found after poisoning by ether, chloral, chloroform, potassium chlorid, arsenic trioxid, or toluylendiamin. It was assumed that the biliary or other pigment was formed in the circulatory system from the coloring-matter of the blood, more especially because most of these poisons are capable of destroying the red corpuscles. More accurate experiments in the poisoning of arsenic trioxid and toluylendiamin have proved that the yellow pigment is formed from an alteration of the hemoglobin of the red corpuscles into bile-pigment; but within the liver, not in the blood itself. This excessive accumulation of biliary pigment can be demonstrated microscopically in the capillary bile-ducts, and a part of it passes into the circulation by a process which will subsequently be described. Again, it was shown that in some cases of poisoning the destruction of red corpuscles was so extensive that the liver was incapable of altering all the hemoglobin to bile-pigment, so that a part of it had to be eliminated as such in the urine. These results explain the connection so frequently observed between other varieties of hemoglobinuria and the frequent combination with icterus. It is therefore advisable to distinguish from the *diffusion icterus* described above all such cases of hematohepatogenous or pleiochromic icterus, and to include under the latter term only those in which we can demonstrate a destruction of the red corpuscles, or a hemoglobinuria.

This modern conception of hematohepatogenous jaundice has obviated the necessity which formerly existed of distinguishing between hematogenous and hepatogenous jaundice by the presence of biliary acids in the latter and their absence in the former. Such a distinction was, however, unnecessary, because cases of obstructive jaundice sometimes present no biliary acids in the urine, and, besides, biliary acids are sometimes found in perfectly healthy individuals.

Géraudel's investigations¹ have markedly clarified our views upon the pathogenesis of icterus. From anatomic investigations of the liver in obstructive jaundice, in which only the periphery of the acinus was preserved, the central portion having degenerated, this writer came to the conclusion that the liver actually consists of two glands, structurally combined but functionally distinct: the portal gland (the periphery of the acinus) and the subhepatic gland (the center of the acinus). The periphery of the acinus produces the biliary constituents, particularly the biliary pigment, and throws them back into the liver blood-stream. The capillary blood-vessels of the liver carry these specific biliary constituents to the subhepatic gland (the center of the acinus), which eliminates them through the biliary passages. The secretion of the biliary constituents into the blood in obstructive jaundice corresponds in a measure to the first step of the physiologic process of bile-formation. Icterus appears because the second step, the elimination by the subhepatic gland, has been interrupted by the closure of the secretory ducts. The writer considers plausible the supposition that the acatectic or diffusion icterus (in acute yellow atrophy of the liver, for example) depends entirely upon the fact that from some cause the eliminating function of the subhepatic gland has been interfered with, while the formation of biliary pigment by the portal gland has not been disturbed. Géraudel's theory also furnishes a simple explanation for the hematohepatogenous or pleiochromic icterus, since it is only necessary to assume that the subhepatic gland is unable to eliminate the biliary pigments which are formed in excessive quantities by the portal gland and secreted into the capillary blood-stream. With such a conception the insufficient elimination is readily understood, whereas if we follow the old theory and ascribe the production and the elimination of the biliary pigments to the same cells, it is hard to see why the biliary pigments are not eliminated as well as produced.

So far we have assumed that the pigmentation which occasions jaundice is real bile-pigment, *i. e.*, *bilirubin*. In most cases this supposition cannot be questioned, for bilirubin can be demonstrated in the urine. But there are numerous other cases in which only *urobilin* (hydrobilirubin) can be found. The latter have been designated as *urobilin icterus*, *i. e.*, icterus due to the deposition of the urobilin in the

¹ Jour. de Physiol., vol. viii, part 1, pp. 69 and 103.

skin. But it is probable that such an assumption is arbitrary because the bilirubin in the tissues may be excreted in the urine as bilirubin: for, in the first place, urobilin possesses a very much slighter coloring power than bilirubin; in the second place, the serum in cases of urobilin icterus always contains bilirubin; in the third place, an enormous amount of urobilin may be found in the urine without a trace of jaundice; and, finally, Leube has demonstrated bilirubin in the sweat of patients with so-called urobilin icterus. The term should, therefore, imply merely that urobilin alone is excreted in the urine, whereas the supposition that the yellowish discoloration of the skin is due to urobilin is probably erroneous. Such a type of icterus is generally of a very mild grade. It is observed especially in cirrhosis of the liver and during the subsidence of ordinary obstructive icterus.

ABNORMAL PIGMENTATION OF THE SKIN

Pigmentation of the skin, as is well known, varies a great deal within physiologic limits. It is most pronounced in brunettes, and more marked upon the exposed body parts of any one, *e. g.*, face and hands, as well as about the genitals and the anus, in the axillæ, on the nipples, and in the linea alba. During pregnancy the pigmentation is generally markedly increased about the areolæ of the nipples and in the linea alba, and, besides, areas of irregular mottling may appear upon the face or other body parts—the so-called “chloasma uterinum” (*chloasma gravidarum*, *masque de la grossesse*).

Ephelides or *freckles* can scarcely be called pathologic pigmentation. Their distribution upon the hands and face, especially in individuals with red hair, and their frequent disappearance during the winter, fall within physiologic limits and have no diagnostic importance.

Itching cutaneous diseases often leave behind a permanent pigmentation, due to the scratching. The characteristic arrangement of this pigmentation in streaks, as well as the history, always points to its origin. It is often decidedly marked between the shoulder-blades in individuals who have suffered from body lice, because these insects seem to have a preference for the folds of the shirt in this region. The so-called “*vagabond's disease*,” sometimes presenting a very dark-brown color (due to serious and persistent infestation with all sorts of vermin and constant scratching, as well as to accumulation of dirt), might in rare instances be confused with Addison's disease.

Melanosarcoma, especially *melanosarcomatosis*, is accompanied by a diffuse gray to black discoloration of the skin and by the excretion of melanin in the urine. (See Examination of the Urine.)

Pulmonary tuberculosis is sometimes associated with a decided brownish coloration of the face or of the entire body. *Measles* occasionally leaves behind traces of its existence in the shape of brownish pigmented spots, whose form and arrangement are sufficiently characteristic for recognition. *Mustard plasters*, *blisters*, and *Baunscheidtismus* produce a localized pigmentation which is sometimes permanent.

Morbus Addisoni causes a smoky-gray to bronze discoloration of the skin, which is the most important diagnostic symptom. Other associated symptoms are: well-marked digestive disorders, *e. g.*, dyspepsia, vomiting, diarrhea; certain nervous symptoms; and a gradually increasing cachexia. The pigmentation usually appears first upon areas

where the pigment of the skin is normally intensified, such as the face, hands, axillæ; also wherever there is any friction upon the skin, such as the waist-line or around the neck. At first a pale, smoky-gray, the discoloration deepens to a bronze-brown, resembling the color of a mulatto, and tiny spots of an intense brown or even black color are observed scattered over this uniformly brown background. The mucous membranes are involved as well as the skin, and although not so commonly observed in the conjunctivæ, a few grayish patches upon the buccal mucosa, especially just inside the lips and cheeks, are rather characteristic of Addison's disease. In well-marked examples of this disease the only parts exempt from pigmentation are the palms of the hands, the soles of the feet, and the nails. To distinguish this affection from *melasicterus*, the urine should be tested for bile-pigment; it is invariably present in the latter. The mucous membranes of the mouth should also be examined for pigmentation spots; they are commonly present in the former. The patient's history and his general condition will clinch the diagnosis. The pigmentation which is occasionally observed in pulmonary tuberculosis may be a source of error, especially since patients afflicted with Addison's disease often suffer from pulmonary tuberculosis as well. The selection of the mucous membranes, the progressive nature of the pigmentation, as well as the entire symptom-complex in morbus Addisoni, usually facilitate a distinction. That the pigmentation observed in pulmonary tuberculosis is closely related to that of Addison's disease is evidenced not only by their similarity, but also by the fact that severe cases of pulmonary tuberculosis exhibit border-line symptoms with Addison's disease and almost constantly reveal histologic changes in the suprarenal bodies.

It is well to caution the reader that, although this pigmentation of the buccal mucous membranes is one of the most characteristic signs in morbus Addisoni, an identical appearance is sometimes observed in perfectly healthy brunettes, and particularly along with the pigmentations associated with diseases of the liver (see the following).

Hepatic cirrhosis and some of the other liver diseases occasionally exhibit a peculiar brownish discoloration of the skin, which differs from icterus in being rather more of a dirty-gray shade and somewhat spotted in arrangement. The absence of bile-pigment in the urine and of a yellowish tinge in the conjunctivæ will prevent any mistake. The cause of this pigmentation is as yet undetermined, but since the description of bronzed diabetes its occurrence has acquired a certain importance. *Diabète bronzée*, first described by the French, presents a combination of diabetes, hepatic cirrhosis, and pigmentation of the skin. In the cases observed by the author there was neither pigmentation of the mucous membranes nor any of the intense brownish-black spots of pigment so characteristic of Addison's disease, although both symptoms may be present in this affection. The presence of glucose in the urine, the demonstration of cirrhosis of the liver without icterus, and the lack of the characteristic symptom-complex of Addison's disease will ordinarily very readily determine a diagnosis.

The continued administration of silver or arsenic preparations is sometimes responsible for a dark pigmentation of the skin. *Argyria* depends upon the deposition of metallic silver, not only in the internal organs, but also in the skin and mucous membranes. It may look like

Addison's disease, but is not associated with any symptoms of illness. Besides, the nails are discolored as well as the rest of the integument. To-day silver nitrate is employed so little in the therapy of nervous diseases that this form of pigmentation is of very rare occurrence. *Arsenic melanosis* is very much more difficult to distinguish from Addison's disease, for the small dark spots scattered about in the diffuse pigmentation, the involvement of the mucous membranes of the mouth, and, in fact, all the peculiarities of Addison's disease have been observed to follow the persistent use of arsenic. The pigmentation itself seems to be derived from the blood-coloring matter. A further difficulty in differential diagnosis depends upon the fact that the arsenic has generally been employed for some cachectic condition, *e. g.*, pernicious anemia, so that the accompanying history will not always solve the difficulty. If the pigmentation diminishes after the arsenic has been stopped, as in a case observed by the author, the diagnosis could be made with probability. We must acknowledge, however, that even very small doses of arsenic sometimes cause arsenic melanosis and that stopping the drug does not always diminish the pigmentation.

[Thirteen cases of *ochronosis* (a total of 14) have been described since Virchow first named this very rare condition in 1866.¹ The light brown to deep black coloration depends upon a staining of the cartilages and fibrous tissues. This characteristic serves to distinguish it from the pigmentation of the skin itself just described in Addison's disease; although in one of the cases, Pope's,² the face showed a marked resemblance to this latter affection and an autopsy revealed disease of the suprarenal glands. The collection of color so characteristic of *ochronosis* is a semilunar or V-shaped patch of brown to black, and is situated in the sclerotic coat just outside the edge of the cornea. The next most characteristic situation is the cavity of the antihelix. Here the coloration is more bluish or leaden black. Other situations are, the costal or any cartilages, the tendons of the wrists, and the fibrous tissue of the palms of the hands. Four of the reported cases had chronic arthritis, and Osler mentions the peculiar gait, "a curious waddle in walking," of 2 of the cases seen by him. In 9 cases the excretion of dark urine or of urine which became black on standing has been described as continuous or intermittent. Three of the cases have exhibited a definite carboloria, and 4 of them an alkaptonuria. The relationship between the latter and *ochronosis* was first suggested by Albrecht.—Ed.]

The reader is referred to text-books upon skin diseases for the consideration of the numerous cutaneous affections accompanied by pigmentation, *e. g.*, *naevus pigmentosus*, *lentigo*, *albinismus partialis* and *universalis*, *vitiligo*, and *peliosis*.

MOISTURE OF THE SKIN; SWEAT EXCRETION

An abnormally dry skin will be observed in any condition where the amount of water absorbed by the digestive organs is limited, or where a large amount of water is removed from the body in some other way than by means of the sweat-glands, *e. g.*, profuse diarrhea, excessive vomiting, digestive diseases with diminished absorption, diabetes mellitus and insipidus, chronic nephritis with polyuria, marked edema of the skin, etc. An increased production of sweat is observed in certain

¹ Virchow's Arch., 1866, vol. xxxvii, p. 212.

² [The Lancet, January 6, 1906, p. 24, contains a table of 11 cases and a colored illustration.—Ed.]

³ [The fourteenth case is reported by Reid, Osler, and Garrod in the Quarterly Journal of Medicine, vol. i, No. 2, p. 199. An excellent colored plate accompanies their description.—Ed.]

fevers, especially in acute articular rheumatism, acute polyneuritis, and epidemic sudamina.

The excretion of sweat is one of nature's methods of cooling the body, under both physiologic and pathologic conditions. When the temperature in any febrile affection drops rapidly, whether spontaneously or under the influence of drugs, a profuse sweat usually accompanies the fall, *e. g.*, at the crisis of pneumonia, at the drop of temperature in malaria, and during the third week of typhoid fever, when the temperature begins to remit. The hectic sweats of phthisis, which are so annoying and prognostically serious, coincide with the fall of temperature. They usually occur at night or in the early morning. In some patients, to be sure, they are independent of any fever and, like the increased pulse-rate, are merely a symptom of tuberculous intoxication. They are generally associated with a sense of considerable weakness,

Fig. 13.—Crystals of nitrate and oxalate of urea obtained from deposits upon the skin (after Leube).

probably connected with the vascular relaxation from the loss of water, for copious draughts of water sometimes counteract them.

We may also mention the sweating produced by hot baths and hot drinks, by pilocarpin, by ammonium acetate, and by most antipyretic measures. Salvia, atropin, eumydrin, agaricin, camphoric acid, and sulphonal, on the contrary, check the sweat secretion.

In certain types of nephritis, interference in renal activity is associated with an increased production of sweat, and sometimes with the deposition of crystalline scales of urea upon the skin (Fig. 13), particularly of the face. To recognize these crystals, the deposit should be scraped off upon a glass slide, dissolved in dilute nitric or oxalic acid, and then allowed to evaporate. Crystals of sodium chlorid are often found instead of urea. As a general rule, especially with much edema, nephritic cases are associated with a diminution in the sweat production.

The sweat in jaundice may be colored yellow. In other conditions different colors have been noted, although not explained (chromidrosis). The most frequent is brownish-red sweat; its etiology is unknown. Blue sweat has been described, and is probably due to the growth of the *Bacillus pyocyaneus* in the skin. Naturally, variously colored underclothes may be a cause of coloring the sweat, especially since the use of anilin dyes has become so universal. Bloody sweat (hemidrosis) has undoubtedly been observed. It is exceedingly rare, however, and the conditions under which it occurs are obscure and by no means uniform.

SWELLING AND EDEMA OF THE CUTANEOUS AND SUBCUTANEOUS TISSUES

Swelling or turgidity of the skin depends upon an increase in the amount of fluid contained in its tissue, i. e., of the blood and lymph. *Increased turgidity* accompanies plethora, fever, and all conditions associated with an increased supply of blood to the skin, or with circulatory excitement. *Diminished turgidity* accompanies all conditions associated with a diminished amount of fluid in the skin, e. g., cachexia and an impoverishment of the general watery elements of the body. *Increased turgidity* presents an increased fulness, a rounded outline of the surface; it obliterates the lines, especially of the face, and is generally combined with a deepening of the fleshy tint. *Diminished turgidity* is characterized by sharper outlines of the parts and by pallor. With the poverty in fluid the skin loses some of its elasticity, and the wrinkles and lines of the face are emphasized.

Anasarca, general dropsy or edema of the skin, means the pathologic increase of fluid in the lymph-spaces and subcutaneous tissues. The difference between edema and turgidity is one of degree. Despite the increase of fluid, the elasticity of the skin is diminished in edema, as is evidenced not by the wrinkles, but by the so-called pitting of the skin on pressure.

Edema always indicates an obstruction to the flow of lymph, with some lack of proportion between its influx and exit, so that an equilibrium is obtained only after the high pressure has distended the meshes of the tissues.

According to Starling, the factors which coöperate, usually in manifold combinations, to produce cutaneous turgidity and edema are:

1. Factors which cause increased transudation:

(A) Increased capillary pressure from—

- (a) Venous obstruction.
- (b) Vasodilatation.¹
- (c) Plethora.

(B) Increased permeability of the capillary walls from—

- (a) Local injury by mechanic, thermic, or chemic agencies.
- (b) Nutritive disturbances of the capillary walls.
- (c) General injury to the capillary walls by circulating poisons.

(C) A watery condition of the blood (hydremlia).

2. Factors which cause diminished drainage or absorption of the fluid in the tissues.

(A) Disturbances of drainage through the lymphatic vessels due to—

- (a) Paralysis of the extremities.
- (b) Closure of the lymphatic trunks.

(B) Disturbances of absorption through the veins due to—

- (a) Venous obstruction.
- (b) A watery condition of the blood.
- (c) A highly concentrated transudate.

As previously stated, to produce edema it is almost always necessary for several of these agencies to act together. The diminution of the elasticity of the tissues (Landerer) must also be mentioned as an additional factor.

Moreover, in addition to the purely physical and chemical factors, cited in the above scheme, which affect the permeability of the capillaries, we must also bear in

¹ In order that vasodilatation should increase capillary pressure, it is necessary that the arteries but not the capillaries be dilated, and even then the result is dependent upon certain quantitative conditions.

mind the conditions affecting the permeability of the endothelia themselves. The influence of the capillary tonus, which is under nervous control¹ and regulates the size and possibly also the shape of the capillary stomata must be considered as well. The influence of the latter factor has been pointed out particularly by Meltzer, whose excellent comprehensive presentation of the modern theory of edema² will well repay perusal.

ALTERATIONS IN THE CUTANEOUS TURGIDITY

Almost all the appearances which the laity, or we as physicians, designate by the terms "run down," "worn out," etc., depend upon alterations in the turgidity of the skin. The marks of worry, excessive fatigue, fever, collapse, or anything else which mars the beauty of a face depend upon alterations in the turgidity of the skin. The existence of fever is often revealed by an increased turgidity of the skin of the face. Exophthalmic goiter is also characterized by increased turgidity, although emaciation may mask the appearance. In emaciation, pallor, cyanosis, edema, other factors beside turgidity are responsible for the appearances. Diminution in turgidity plus depression of the mimic faculty is responsible for the characteristic facial expressions of the *moribund* and for the so-called *facies Hippocratica* accompanying intestinal obstruction, peritonitis, cholera, etc. In the latter the features seem sunken; the wrinkles and lines of the face more pronounced; the nose sharp; the eyes fallen deep into their sockets; the skin is cool, even cold, and damp with cold sweat; while the color is pale and dusky with cyanosis. In diminished turgidity the wrinkles are very plainly marked on the trunk, especially in cholera morbus or "cholera infantum," where the organism has been deprived of so much water. Oftentimes in cachexia, where the subcutaneous fat is also diminished, the wrinkles become even more marked. A certain grade of diminished turgidity is a physiologic accompaniment of advanced age and senility.

EDEMA

Edema presents a plump swelling and a tense, shiny appearance of the surface of the skin; it obliterates the wrinkles, the hollows, and the normal bony prominences. When the edema suddenly disappears, the epidermis exhibits fine lines and creases and perhaps scales off. When quite fresh, edema often imparts an increased transparency to the skin. Over certain regions, especially the thighs and abdomen, transparent lines or streaks may appear, following the grain of the skin and resembling *striæ gravidarum*. These lines may remain permanently, even after the disappearance of the edema. They are due to a stretching and distention of the connective tissues and lymph-spaces. Very pronounced edema, especially over areas exposed to considerable mechanical irritation, may be associated with the formation of blebs and blisters in the external layers of the epidermis. If these burst or are opened artificially, a thin fluid will ooze from microscopic openings of the inner surface, sometimes persisting quite indefinitely. As is natural, the danger of infecting these tiny lacerations is considerable, and, of course, serious.

Edematous skin is usually pale because the blood-vessels are compressed by the pressure of the lymph, and the same amount of blood

¹ Nerve-endings have been demonstrated in the capillary walls by S. Mayer.

² American Medicine, 1904, vol. viii, Nos. 1, 2, 4, 5.

must be spread over a greater area. Inflammatory edema and edema associated with cyanosis are exceptions to this rule.

Pitting of the skin is quite essential for the diagnosis of edema. It is due to a loss of the cutaneous elasticity, from the distention of the meshes of the tissues by the lymph. Where the skin is very elastic and easily stretched, as on the face or prepuce, the imprint of the finger may vanish almost immediately. Children's skin is so much more elastic than adults' that, even over other parts, pitting may sometimes be wanting. Again, brawny edema which has persisted for some time may pit with difficulty, because there is a certain amount of connective-tissue growth. We notice this particularly in inflammatory edema and in the chronic edema of the lower extremities, which is sometimes converted to elephantiasis.

Edema may be classified etiologically into four varieties:

1. Edema from circulatory stasis, where it may be combined with other transudations, especially into the serous cavities.
2. Edema from disturbances of the renal function, where hydrops may be present elsewhere.
3. Edema from inflammation.
4. Edema from angioneurotic disturbances.

Obstructive or Circulatory Edema.—To explain the origin of general obstructive edema in cardiac patients in accordance with the statements made upon page 49, the following factors must be considered. The slowing of the circulation diminishes the nutrition and the tonus of the capillary walls, making them more permeable, and this effect is most noticeable in those parts most remote from the heart, where, from encountering increased resistance, the circulation is poorest. This increased permeability is also particularly marked in the most dependent portions of the body, from purely hydrostatic reasons, the capillary pressure being directly proportional to the superincumbent column of blood. In these situations we find the first accumulation of fluid in the tissues, because the lymphatics and the venous portions of the capillaries are unable to keep pace with the increased transudation. As an additional factor in a certain degree of obstruction there is also an increase of pressure in the large veins which empty into the heart and receive the lymph from the great lymphatic trunks; this increase of pressure hinders the discharge of lymph into the veins, and thus favors the accumulation of fluid in the tissues. An older explanation of obstructive edema recognized as the only cause the increased venous pressure and the consequent diminished absorption of the lymph in the tissues.¹ The preceding theory, on the contrary, lays the greatest stress upon the augmented permeability of the capillary walls, and takes cognizance of the fact that the general venous pressure is sometimes excessively increased without a trace of edema and that edema may exist with obstructive conditions in which the venous pressure is not increased (vasomotor obstruction, cardiac obstruction with dilated veins). An explanation based solely upon the pressure relations is, therefore, inadequate. The more recent theory is also favored by the fact that it agrees with Meltzer's views in reference to the influence of the capillary tonus upon permeability (see p. 50), and may be used without modification to explain those cases of circulatory disturbance with edema in which there is no demonstrable interference with cardiac dynamics but in which the obstruction is due simply to the vasomotor system.

Any affection of the heart or of the lungs which will produce cyanosis from congestion may also produce obstructive edema. The edema

¹ This view is founded partly upon a confusion of the conditions existing in general venous congestion with those present in local venous congestion produced by the local obstruction of a venous trunk. In the latter the venous pressure above the obstruction is considerable (almost equal to the arterial pressure) because the vein has been transformed, as it were, into a blind manometric appendage of the capillaries and arteries. In general venous obstruction, on the other hand, the venous pressure is in many cases not raised at all or at most the increase of pressure is limited directly to the area up stream from the heart.

begins and becomes most intense in the body parts most remote from the heart and where the capillary walls are most influenced by hydrostatic pressure due to the dependent position of the part, *e. g.*, the hands, the feet, and, in the recumbent posture, the loins (see above). In obstructive conditions the hydrostatic pressure of the blood-column exerts a particularly marked influence; for all these conditions are characterized by a fall of capillary pressure in the general circulation in those positions subjected to the least hydrostatic pressure. The author emphasizes this fact because it is in opposition to some existing hemodynamic theories. Obstructive edema appears late in the face, principally because the arterial and venous blood-columns exert a hydrostatic suction upon the capillaries of this region. Nevertheless there are exceptions to these rules of localization which are not very well understood and probably depend upon vasomotor phenomena. The influence of gravity upon the distribution of the edema becomes very evident with change of posture; *e. g.*, ambulatory patients will

Fig. 14.—Haygarth's nodosities. Case of arthritis deformans (Dr. J. M. Jackson, Massachusetts General Hospital).

suffer from edematous feet; but upon going to bed the edema soon disappears from the extremities and appears in the region of the loins. Lying upon one side for a considerable time will distribute the edema to that side of the body, and, if a hydrothorax be present, will make it more marked upon that side.

When the obstruction is local, the edema will, of course, be confined to the region from which the obstructed vein arises. The edema due to local venous obstruction depends upon an increased pressure in the capillaries (distinguishing it from that due to general obstruction), upon the increased permeability of the capillary walls resulting from the failure of the circulation, and in the more dependent parts upon the lymphatic pressure of the blood-column.

A fluid exudate in the abdominal cavity, due to portal obstruction (cirrhosis, thrombosis) or to a chronic affection of the peritoneum (tuberculosis), will sometimes compress the vena cava inferior or the common iliac veins, and so give rise to an edema of the lower extremities. To decide the true nature of this symptom-complex is often very

difficult, for both ascites and edema of the lower extremities may be coördinated sequences of some general obstruction located in the thorax. The onset will sometimes permit a differentiation. If the abdomen swelled before the legs, the cause will be one of the above-mentioned affections of the abdominal cavity; if the legs swelled before the ab-

Fig. 15.—Heberden's nodes in arthritis deformans (New York City Hospital).

domen, the cause will be some general circulatory disturbance. The history of the case not infrequently leaves us in doubt.

Renal or Nephritic Edema.—Magnus' experimental researches¹ indicate that hydremic plethora, *i. e.*, an increased volume of the blood due to retention of its water (formerly considered a sufficient cause

Fig. 16.—Heberden's nodes and ulnar deformity. Case of arthritis deformans (New York City Hospital).

for the production of nephritic edema) may be the cause (although not the only one) of edema and of other transudations if the vessel-walls be coincidentally damaged and rendered abnormally permeable. This latter condition occurs in renal disease from the retention of the urinary solids, and may be produced experimentally by the simultaneous ligation

¹ Arch. f. exp. Path., 1899, vol. xlii.

of both ureters. Only when such a retention exists is it justifiable to assume nephritic edema as the result of hydremic plethora. It should also be noted that the retention of urinary solids requisite to the development of nephritic edema, in addition to injuring the vessel-wall, as indicated by Magnus, may also favor edema by making the tissue-juices hyperosmotic. This is due partly to an accumulation of the metabolic products of the tissues and partly to the transudation of the constituents of the blood which are not eliminated, particularly sodium chlorid. The hyperosmotic fluid attracts the water from the blood.

Nephritic edema, contrasted with the variety due to congestion, is practically independent of the influence of gravity and of the distance of the affected part from the heart. This is due to the fact that the circulation is normal and that the fall of capillary pressure peculiar to general obstruction is not present in nephritis, so that the hydrostatic pressure of the blood-column does not markedly overload the capillary blood-vessels. Its location seems rather to depend upon some peculiar arrangement of the lymphatics in the different parts of the body. Nephritic edema (in acute and subacute nephritis) is a typical example of this selective action, appearing generally in the face, and especially about the eyelids. Edema localized in this way is very suggestive of the diagnosis of nephritis. The more chronic types of nephritis (contracted kidney), however, rarely exhibit any edema until quite late in the disease, and then it usually begins in the feet, because the hypertrophied heart, unable to maintain the circulation against the obstacles in the kidneys and at the periphery, begins to flag. In other words, in these very chronic cases of nephritis dropsy is generally of cardiac origin.

In addition to its early appearance in the face, true nephritic edema is further characterized by the fact that cyanosis is absent, but the possibility of the occurrence of mixed forms must also be borne in mind.

Cachectic Edema.—Under this title are usually included those edemas observed in severe cachexias and particularly those occurring in anemic individuals where there are no pronounced cardiac or renal affections. The latter class is also designated as anemic edema. It is scarcely possible to explain cachectic edema by any one theory, for the factors responsible for obstructive and nephritic edema are evidently active in manifold combinations. It is but natural to suppose that the general disturbance of function in cachectic conditions also affects the heart and the kidneys. We can no longer describe this group of edemas as anemic or hydremic, because neither anemia (or oligochromemia) nor hydremia is present in all these cases; besides experimental investigations indicate that neither oligochromemia nor hydremia is in itself sufficient to produce edema. Even in those cases where we have reason to believe that hydremic plethora as well as hydremia and oligochromemia exist, Magnus' investigations mentioned above show that an additional factor is necessary for the production of edema, namely, increased permeability of the walls of the vessels. Upon the other hand, it is clear that oligochromemia and hydremia, particularly when of long duration, may play an etiologic rôle in these cachectic edemas, since in addition to causing functional disturbances of the circulation and of urinary excretion they may damage the vessels and increase their permeability. According to this conception, cachec-

tic edema will at times simulate the type of nephritic edema, at others that of cardiac or obstructive edema.

Inflammatory Edema.—From the diagnostic point of view inflammatory edema is only important in pointing to some deep-seated inflammation. It must be attributed to the saturation of the neighborhood of an inflammatory focus with the fluid components of the exudate (Samuel).

It is of more interest to the surgeon than to the clinician. Although so rarely present, it is important in suggesting the purulent nature of an underlying pleuritic effusion. In acute articular rheumatism the inflammatory edema about the joints is quite as important as the effusion in the joint itself. Inflammatory edema may aid the surgeon in recognizing a deep suppuration, as in purulent perforative appendicitis, liver abscess, etc. Here it would depend upon adhesions which connect the inflammatory focus with the skin.

Angioneurotic Edema.—Under this heading are included certain rare types of edema of the face or of other areas of the skin. Some of them are combined with analogous conditions in the mucous membranes (laryngeal, bronchial, gastric, or intestinal). On account of their acute origin and rapid *disappearance*, they have been regarded as products of angioneurotic disturbances. The edema of the tongue in Rogowicz's experiments may explain angioneurotic edema. This edema resulted from a maximum dilatation of the lingual vessels and was produced by dividing the vasoconstrictor fibers running with the hypoglossal nerve and simultaneously stimulating the vasodilator fibers which reach the tongue through the lingual nerve. The most probable supposition is that this maximum dilatation of the vessels increases the formation of lymph, raises the capillary pressure, and at the same time renders the capillary walls more permeable. The edema of cyanotic parts should also be included under this heading (see p. 42, et seq.: *Edème bleu des hystériques*).

A similar conception possibly applies to some of the edemas occurring in nervous diseases (see Examination of the Nervous System), and to the rapidly appearing circumscribed wheals of urticaria, which are due to local edema and seem to hold a certain etiologic relationship to the previously mentioned idiopathic form. It should, however, be noted that in nervous diseases ending in paralysis (polyneuritis, for example) the loss of motion of the parts has something to do with the occurrence of edema, since it leads to stasis. For the explanation of the origin of urticaria-like edema we must bear in mind the effect of certain organic substances, classified by Heidenhain as the first group of lymphagogues, the action of which is probably due to their influence upon the permeability of the capillary endothelial cells. The type of these substances is furnished by an infusion of crab-meat.

It is difficult to classify the general edema which occurs without nephritis in certain infectious diseases, especially in scarlet fever and diphtheria, as well as that appearing after the injection of diphtheric antitoxin, and that after the employment of potassium iodid.

THE DETERMINATION OF THE ELECTRIC RESISTANCE OF THE SKIN

When the ordinary galvanometers or voltmeters are employed, the determination of the resistance of the body to electric conduction, which resistance is manifested practically by the skin, does not play an important part in electrodiagnosis (see

later). With a galvanometer graduated in milliampères, the cutaneous resistance is naturally included in the measured strength of the current, and if we measure by volts, no attention whatever is paid to the resistance.

The determination of the electric resistance of the skin is, however, of great theoretic and practical interest in exophthalmic goiter and in scleroderma. In the former affection the cutaneous resistance to electric conduction is almost constantly diminished. The explanation ordinarily given, that this phenomenon is due to the increased moisture of the skin, seems doubtful to the author because such a diminution of resistance cannot be obtained in health by flooding the skin with water, and furthermore because the cutaneous resistance to conduction is not diminished in diseases characterized by hyperidrosis, such as phthisis, for example. In doubtful cases this diminution of cutaneous resistance may be of diagnostic value in the recognition of exophthalmic goiter. Upon the other hand, the cutaneous resistance to electric conduction is increased in scleroderma; in these cases there is no doubt that the phenomenon is to be explained by the thickened and dry condition of the integument.

According to Dubois, we must differentiate between the resistance offered by the body to the continuous galvanic current, the resistance to the interrupted galvanic current (immediately after the opening and the closing of the circuit), and the resistance to the faradic current. For the question under discussion we are interested only in the resistance to the continuous galvanic current, since the remaining kinds of resistance have not yet been sufficiently determined and since the above statements in regard to exophthalmic goiter and scleroderma refer to the continuous galvanic current.

From a technical standpoint the cutaneous resistance may be determined by any of the methods employed in physics, but some of these are cumbersome and hence the following is recommended on account of its simplicity. Modern electric outfits are usually provided with some means for measuring the voltage as well as the strength of the current. Now from Ohm's law it follows that an absolute measure of the resistance is obtained in ohms by dividing the voltage by the strength of the current. To determine an increase or decrease of the cutaneous resistance in a given patient we employ the same source of electricity, the same electrodes, and apply them to analogous portions of the body first of the patient and then of the control, a healthy individual. According to Ohm's law, the resistance is inversely proportional to the strength of the current; and the latter is read from the galvanometer in each case. The stronger the current from the same source of electricity in the patient, as compared with that in the control individual, the less the resistance; with twice the current the resistance becomes one-half, with three times the current one-third, and so on. This method is usually sufficient for clinical purposes, particularly when the precaution is taken to employ not only one but several healthy individuals of the same age for comparison. Electrodes of the same size must, of course, be employed and they must be applied to analogous portions of the body, since the resistance to the constant current is inversely proportional to the size of the electrode and since this resistance varies greatly in different cutaneous areas. As the resistance may vary at different times in the same individual, such comparative tests are of diagnostic value only when the difference is considerable. As a matter of fact, the variations from the normal observed in exophthalmic goiter and scleroderma are frequently enormous.

In these determinations, however, still further difficulties are encountered, since the resistance is markedly influenced not only by momentary variations in the voltage, but also by the length of time during which the current is employed. Comparative results can consequently be utilized only when the same voltage and the same length of time are used. Still more accurate results will be obtained by allowing the current to act until the minimum resistance is reached. This minimum, however, varies according to the voltage—the stronger the voltage the smaller the minimum. For every voltage there is consequently a minimum of resistance, which is reached after a certain period of time and which is known as the relative minimum of resistance for the particular voltage employed. This minimum does not decrease indefinitely, but ultimately reaches a point beyond which it remains uninfluenced by further increase in the voltage. This point is designated as the absolute minimum of resistance, and by this we mean the least resistance which it is possible to obtain in any given case by increasing the voltage. In health the absolute minimum of resistance is usually reached with a voltage of 30 to 50, and by an electrode with a surface of 64 to 100 square centimeters.

In exophthalmic goiter Martius, Oppenheimer, Kahler, and others have found that:

1. The absolute minimum of resistance is very low.
2. This absolute minimum is obtained by a low voltage.
3. The relative minimum of resistance for a lower voltage is abnormally low.

The author adds to this that the minima are also usually attained after an abnormally short period of time.

In the Bern clinic the author usually determines the relative minimum of resistance for different voltages up to 10. Two electrodes are employed, each having a surface of 100 square centimeters; they are well moistened and firmly pressed against the abdomen and the lumbar region respectively. Parts with thickened epidermis, as the soles of the feet, are, of course, poorly adapted for these examinations, since the resistance in such situations is markedly influenced by the thickened epidermis and but feebly so by the current.

The following examples are given:

Exophthalmic goiter, electrodes, 100 square centimeters, to the abdomen and back.

Number of Elements.	Volts.	Milliampères.	Relative Minimum of Resistance (Ohms).	Relative Minimum of Resistance (Ohms) in a Normal Person.
2	2.5	1.0	2,500	10,000
4	5.0	3.4	14,706	6,875
6	7.5	7.6	986	4,444
8	10.0	13.0	769	2,615
10	12.0	20.0	600	15,129

Scleroderma (according to H. Schnyder).

RELATIVE MINIMUM OF RESISTANCE IN OHMS

Volts.	Nuchal-Frontal Region.	Nuchal-Anterior Cervical Region.	Arm-Forearm.	Both Palms.	Both Soles.
	Normal	Normal	Normal	Normal	Normal
1.38	14,000 (7333)	14,000 (14,000)	28,000 (5600)	28,000 (1500)	5600 (2000)
4.20	11,633 (1663)	14,000 (4,536)	42,000 (3185)	19,000 (1500)	6000 (2000)
8.30	5,375 (521)	8,600 (1,374)	22,631 (1219)	21,500 (1500)	6000 (2000)
14.00	2,978 (609)	11,833 (634)	22,903 (1500)	6714 (2000)

EMPHYSEMA OF THE SKIN

This is due to the presence of gas (generally air) in the meshes of the subcutaneous tissues. Upon mere inspection, emphysema of the skin resembles edema. Palpation, however, over emphysematous regions produces a peculiar crackling, audible as well as palpable. It is due to the movement of bubbles of air in the tissues. Percussion elicits a tympanitic note. (See Percussion.)

In very rare instances the gas is developed in the skin by the activity of gas-producing bacteria, *e. g.*, in *anthrax* and in *malignant edema*. In most cases air penetrates the subcutaneous tissues from the rupture of some air-containing organs or from some external wound. The most frequent source is through the mediastinal connective tissue, resulting from an ulcerative destruction of the esophageal wall (carcinoma) or from a rupture of the pulmonary alveoli (following coughing or external trauma). The emphysema will then first be noted at the lower part of the neck or over the manubrium. In a patient with a tracheotomy wound, air may be forced under the skin by a fit of coughing. The chief diagnostic significance of cutaneous emphysema is its dependence upon the rupture of some air-containing viscus. If the source persist,

the entire body surface may be swollen; but ordinarily the air is readily absorbed and the cutaneous emphysema disappears.

Fig. 17.—Emphysema of left breast and chest-wall, due to broken ribs (Massachusetts General Hospital).

CUTANEOUS HEMORRHAGES

Hemorrhages into the skin appear as spots of variable size, at first red, later violet to black, gradually changing to green and yellow, and finally disappearing. These changes in color are due to the alterations in the blood-pigment. In contrast to hyperemic spots, cutaneous hemorrhages do not disappear under pressure. They are not usually elevated except in certain types of *purpura*, where the epidermis may be raised like a bleb. Absorption of the hemorrhagic spots usually begins in the center. When small, pin-point in size, they are called *ecchymoses* or *petechiæ*.¹

Cutaneous hemorrhages occur:

1. From *trauma* (ordinary black-and-blue spots). The ecchymoses caused by *flea-bites* (*purpura pulicosa*) belong to this group and may be mistaken for a form of *purpura*. They are, however, unlike *purpura*, found most abundantly upon the trunk. They frequently exhibit the bite-mark as a dark spot in the center of the hemorrhage, and when

¹[We usually characterize the larger, more or less irregularly shaped spots as ecchymoses, and limit the term petechiæ to those pin-point in size.—Ed.]

fresh, they are surrounded by a hyperemic zone, the color of which will disappear upon pressure.

2. Spontaneously, in *all severe cachexias and infections* which are associated with a hemorrhagic diathesis; particularly as a characteristic symptom in the various types of *purpura*, in *grave anemias*, especially in *pernicious anemia*, *leukemia* and *scurvy*, in *acute yellow atrophy* of the liver, in *phosphorus-poisoning*, in *ulcerative endocarditis*, in *pyemia*, and

Fig. 18.—Purpura (New York City Hospital).

in *nephritis*, and in the *terminal stages* of certain cases of *pulmonary tuberculosis*.

3. In the hemorrhagic forms of the *acute exanthemata*: *scarlet fever*, *measles*, *small-pox*. These are notoriously more serious and critical than the ordinary types, especially "black small-pox," where the hemorrhage occurs in the interior of the pustules; and still more so that rare, very fatal form, "*purpura variolosa*," where extensive cuta-

neous hemorrhages occur without the formation of any rash. But there are some cases of measles and scarlet fever which are not much more serious than the ordinary cases, although they are shown to be hemorrhagic by the fact that the coloration of the rash does not entirely disappear upon pressure, and that even during the convalescence slight remains of the rash still show as a pigmentation.

Erythema nodosum (contusiforme) not infrequently simulates bruises of the skin, presenting rather extensive cutaneous hemorrhages upon the extensor surface of the extremities.

4. From *marked venous stasis*, especially when accompanied by severe paroxysms of cough, which suddenly increase the congestion, *e. g.*, *pertussis*, where hemorrhages in the mucous membranes, particularly in the conjunctivæ, are not uncommon.

COLLATERAL CIRCULATION IN THE SKIN

A visible distention of veins or arteries in the skin often suggests some deep-seated obstruction to the circulation, *e. g.*:

Fig. 19.—Collateral circulation in the abdominal wall (New York City Hospital).

I. The collateral circulation (arterial) when the aorta is occluded at the isthmus. (See Congenital Heart Diseases.)

II. The collateral circulation (venous) upon the anterior thoracic wall. This is of some importance in diagnosing mediastinal or pulmonary tumors, which compress the big veins within the chest, especially the vena cava superior and inferior. Here the intercostal and internal mammary veins dilate and furnish a channel of communication between the two venæ cavæ when either one is occluded.

III. The very striking collateral circulation in the abdominal wall caused by thrombosis of both iliac veins or of the vena cava inferior

Fig. 20.—Collateral circulation in thrombosis of the vena cava inferior.

(Fig. 20). The blood from the lower extremities, and even from the kidneys, reaches the thorax by way of distended tortuous veins, which are arranged longitudinally and are more pronounced upon the sides than upon the front of the abdomen. This selection of the sides of the abdomen is of some importance in distinguishing this form of obstruction from the next.

IV. The collateral circulation caused by obstruction of the portal veins (cirrhosis of the liver or portal thrombosis, Fig. 21). In the latter

case it is furnished by anastomoses between the tiny veins at the root of the mesentery and those of the peritoneal covering and suspensory ligaments of the liver, even sometimes by a patent vena umbilicalis. In this latter type of anastomosis the distended veins of the abdominal wall are apt to be very characteristically arranged about the navel, forming the so-called "caput medusæ."

Figs. 20 and 21 illustrate the diagnostic distinction between the distention of the abdominal wall veins, due in the one case (Fig. 20) to

Fig. 21.—Collateral circulation in thrombosis of the portal vein or in hepatic cirrhosis.

obstruction in the vena cava, and in the other case (Fig. 21) to obstruction in the portal system. Numerous exceptions make this distinction less valuable for diagnostic purposes, *e. g.*, when ascites follows portal stasis the presence of the fluid in the peritoneal cavity will naturally produce a secondary obstruction in the vena cava, and collateral veins will form on the sides of the abdomen.

In any of these cases of collateral venous circulation it is always important to determine the direction of flow of the venous blood. This

is readily done, particularly when the valves of the veins are intact, by emptying the blood from the vein by means of pressure with the fingers, and then, when the pressure is removed, by watching, first at one end and then at the other end of the vein, to see from which direction the blood comes first. If there be no valves or if the valves be incompetent, this test is valueless, because the blood would stream back with equal rapidity from either end.

A very fine, irregular, dendritic enlargement of the thoracic skin veins is often observed in all chronic affections of the lungs and pleuræ, especially when adhesions are present between the two pleural surfaces. It probably represents a collateral circulation between the lung and skin. In the very chronic forms of phthisis it is observed frequently, and then quite often in the supraspinous fossa.

Nearly twenty-five years ago the author described a zone of small dilated cutaneous veins which are arranged dendritically and extend in the form of a band about 1 to 3 cm. broad along the anterior lower border of the lung and over the superficial cardiac dulness.¹ It has no especial pathologic significance, because it is also observed in perfectly healthy individuals; but clinically it represents a rough picture of the position of the lung borders. It may be situated either within or without the pulmonary margins, but is generally near by, unless modified in some fashion, as by pleural adhesions. Percussion-results prove that a low position of this zone corresponds to emphysema of the lungs.

It is very difficult to explain the appearance of this zone of vessels, but, without question, it is due to a difference in pressure between the inside and the outside of the chest-wall. Suppose we take the region where the zone of vessels marks the internal pulmonary hepatic boundary. Above the intrathoracic pressure is negative, and below the intra-abdominal pressure is positive, which, of course, in and of itself explains nothing. Respiration, however, alters the pressure relations (see p. 85 et seq.). It produces a distinctive change of shape in the chest-wall, as evidenced by the normal inspiratory sinking in of the lower intercostal spaces and by the so-called diaphragm phenomenon. Both these conditions furnish an inspiratory, localized, girdle-shaped depression of the chest-wall, which must occasion a rhythmic obstruction to the venous blood-current, because the superficial veins of the depressed parts are compressed by the external atmospheric pressure. Now it is conceivable that this rhythmic congestion may give rise to an area of small distended veins. Perhaps a similar explanation would account for the formation of the zone which surrounds the heart, because evidently similar differences in pressure exist at that portion of the chest-wall against which the heart beats and at that portion against which the lung rests. In fact, one oftentimes sees an inspiratory retraction of the intercostal spaces surrounding the cardiac area, quite similar to that about the lower margin of the lung. Local variations in pressure caused by the maximum distention of the heart and its minimum size during systole would also influence the circulation in the thoracic wall. Paroxysms of coughing were formerly considered to be the most important, if not the sole, cause of this vascular distention. They probably do exert a considerable influence, because during a cough the strong positive pressure from the inside causes a marked congestion of the subpleural and subperitoneal veins. This in turn reacts upon certain cutaneous veins which are connected with the subserous veins, and the congestion will be marked along the lines of attachment of the diaphragm. The latter, to a certain extent, acts as a watershed for the venous blood flowing upward and downward. Every one with a cough does not present this zone of veins, so that we must assume as another factor in its origin a certain indefinite abnormal distensibility of the smallest vessels. As a matter of fact, it is found oftenest in such patients as exhibit a similar tendency to the formation of dendritic venous dilatations in other parts of the skin.

TROPHIC AFFECTIONS OF THE SKIN

The so-called "decubitus" and the trophic disturbances accompanying nervous affections will be considered later under Examination of the Nervous System.

Clubbed fingers, the peculiar swellings of the terminal phalanges of the fingers, are observed in congenital heart disease, in chronic pulmonary diseases, most frequently in bronchiectasis and empyema (hence the name empyema fingers), and less often in phthisis. The deformity may develop within a few weeks and then disappear again when the causal disease has decidedly improved. In the more chronic cases even the bones share in the deformities. The toes are also affected, though less decidedly. As yet we have little accurate information in regard to the mode of origin.

Fig. 22.—Clubbed fingers (Dr. H. H. Mason).

Fig. 23.—Clubbed fingers (Dr. H. H. Mason).

[Clubbed fingers have also been observed in other cardiac conditions, in suppurative processes elsewhere than in the lungs, in syphilis, in hypertrophic biliary cirrhosis, and in diarrheal affections. The close connection between the exhibition of clubbed fingers and the definitely proliferative changes of some of the bones has awakened considerable interest since Bamberger¹ first discussed 11 cases under the heading "Bone Changes in Pulmonary and Cardiac Conditions," and Marie suggested the name "Osteo-arthropathie Hypertrophique Pneumonique."²

The bone changes do not involve the distal phalanges, but more especially the ulna and radius, the tibia and fibula, the metacarpal and metatarsal bones, and very rarely the lower part of the femur. The new bone is usually in layers under the periosteum. The annexed figures (Figs. 22, 23, and 24), especially the skiagram, indicate the appearance very well.

Ebstein³ begins and closes his thorough résumé with a quotation from S. West, "Clubbing is one of the phenomena with which we are all so familiar that we appear to know more than we really do."—Ed.]

ACUTE EXANTHEMATA; CUTANEOUS DISEASES; DERMATITIS MEDICAMENTOSA

Although the scope of this book does not include the subject of skin diseases and the acute exanthemata, it seems fitting, from the standpoint of diagnosis, to describe the rash of typhoid fever, herpes febrilis, miliaria, and the medicinal eruptions.

ROSE SPOTS (Roseola)

These are small, round, very slightly elevated, hyperemic, rose-red

d
c
b

A

B

Fig. 24, A.—Skigram of arm and hand with clubbed fingers: a, Raised periosteum; b, normal bony contour; the space between a and b shows bony proliferation; c, probably a later stage of bony proliferation than between a and b; d, an even more marked bony proliferation of the lower shaft of ulna, the same feature on the inner surface and also on the shafts of the metacarpal bones, especially the second, third, and fourth. A similar, though much less striking, change can be seen on the shafts of the proximal and middle phalanges, but no bony change exists in the terminal phalanges where the clubbing is so pronounced. The styloid processes of both radius and ulna show a osteoporosis (Dr. H. H. Mason, Vanderbilt Clinic, N. Y. City).

Fig. 24, B.—A normal hand for comparison (from L. G. Cole's x-ray laboratory).

spots, varying in size from that of a pin-head to that of a small pea. They appear after the beginning of the second week of typhoid fever.

They are sparingly scattered over the abdomen, more rarely over the chest [back.—Ed.] and extremities. Though most marked at the height of the fever, they may persist throughout its entire course and even after convalescence. Relapses are frequently accompanied by a fresh crop of spots. Their hyperemic nature is shown by their immediate disappearance under the pressure of the finger and their instant reappearance when the pressure is removed. Rose spots are differentiated from the rash of acne by the absence of a decided center. This tip in acne is formed by some cutaneous gland or hair-follicle, or by suppuration starting in one of them. The opening of a cutaneous gland or hair-follicle is only rarely found occupying the center of a rose spot, or a vesicle tipping the center. If in doubt concerning any one spot, we can generally find in a case of typhoid fever other absolutely characteristic rose spots elsewhere upon the abdomen. The spots usually pass through a cyclic development, ripening in the course of two or three days and then fading away, while in the mean time new spots appear in other places. In a doubtful case it is often advisable to mark out with a skin pencil the few spots that appear, in order to observe them carefully at each visit. For although rose spots may never appear during the entire course of some few cases of typhoid fever [the positive evidence of this peculiar rash is one of the safest diagnostic signs of the disease.—Ed.]. (See Plate 1.)

HERPES FEBRILIS

This consists of a group of vesicles $\frac{1}{4}$ to 2 cm. in diameter, situated upon a slightly inflamed base. The watery content of each vesicle

Fig. 25.—Herpes cervicalis: Cerebrospinal meningitis (Dr. E. G. Cutler, Massachusetts General Hospital).

rapidly becomes purulent and turbid, and the vesicle then either bursts or dries up, leaving an irregular, scaly crust upon a somewhat reddened background. Although they may appear anywhere upon the face, nose,

PLATE 1.

Typhoid spots (rose spots) in the region of the umbilicus (natural size)

Rose spots in a case of typhoid fever, showing distribution upon the trunk. The three spots upon the face are rather unusual.

cheek, lip, or ear, they develop most frequently on the outer edge of the lip. According to their position they are called herpes labialis, facialis, nasalis, frontalis, and auricularis. The eruption generally appears at the beginning of febrile diseases; rarely in the later stages. It is most common in those fevers with a rapid onset, particularly in croupous pneumonia.

[Howard¹ demonstrated in two cases of labial and nasal herpes and herpes of the body occurring in acute lobar pneumonia pathologic changes in the posterior-root ganglia, the Gasserian ganglia, and the skin. The changes are apparently identical with those shown by Head and Carpenter² to be invariably associated with *herpes zoster*. J. R. Hunt³ has described a similar picture in connection with the geniculate ganglion.]

From evidence available at the present date, it is probable that lesions identical in character and similarly localized are present in the herpes of other infectious diseases, and in the light of our present knowledge, that the lesions of the sensory ganglia, nerves, and skin are due to the action of the soluble toxins of various micro-organisms.—Ed.]

Herpes is very rarely observed in typhoid fever, but frequently occurs [in malaria.—Ed.] in epidemic meningococcic meningitis and in pneumococcic meningitis, where it is of value in differentiating these varieties from tuberculous meningitis. There is a certain type of slight ephemeral fever, with nothing objective to be discovered except the increased temperature and herpes, which is termed *febris herpetica*. Herpes, as a rule, is considered a relatively favorable prognostic sign (*i. e.*, as compared with cases of the same disease without herpes). Experience in the use of streptococcus toxin in the treatment of malignant tumors teaches that herpes febrilis depends upon a toxic action; yet in the Bern clinic we have several times isolated meningococci by scraping the base of fresh herpetic vesicles in cases of epidemic meningitis.

The author has noted herpes several times in meat-poisoning; hence its appearance may be of some value in distinguishing this affection from typhoid.

MILIARIA (Prickly Heat); SUDAMINA

Under this head are included various eruptions of tiny vesicles developing most frequently upon the abdomen and chest, and usually accompanied by profuse perspiration. It is generally supposed that this eruption is due to the plugging of the orifices of the sweat-glands with swollen epithelium and to the formation of small retention cysts, some of which may be associated with a slight inflammatory reaction in the neighborhood. Three main types are to be distinguished:

Miliaria crystallina (sudamina; crystal rash): absolutely transparent vesicles, resembling a dewdrop and without reddened base.

Miliaria alba: vesicles with slightly turbid contents upon a faintly reddened base.

Miliaria rubra: small red papules with a faintly developed vesicle in the center. This type is apt to itch.

¹ Howard: Amer. Jour. Med. Sci., February, 1903.

² Head and Carpenter: Brain, 1900, Part III.

³ "On Herpetic Inflammations of the Geniculate Ganglion. A New Syndrome and Its Complications," Jour. Nerv. and Men. Dis., February, 1907.

Miliaria vesicles are generally situated close together. It is as yet unknown whether the eruption in the so-called epidemic miliaria has the character of a specific exanthem or is simply the result of the profuse perspiration.

DERMATITIS MEDICAMENTOSA (DRUG ERUPTION)

Numerous medicinal agents have the peculiarity of exciting in certain individuals eruptions which resemble urticaria, measles, or even scarlet fever. The rash generally fades promptly and disappears when the drug is omitted. Examples of such drugs are most of the antipyretics, especially antipyrin, antifebrin, phenacetin; not infrequently sodium salicylate [and quinin.—ED.]; many preparations of balsams, *e. g.*, balsam of copaiba; and mercury used externally, or, in rare cases, internally. The injection of antitoxin may produce similar eruptions resembling urticaria, measles, or scarlet fever. Iodid of potassium is apt to produce a rash which may closely resemble erythema multiforme or to bring out a purulent acne-like eruption which may be confounded with syphilis or small-pox. The prolonged administration of considerable doses of bromid of potassium frequently causes an eruption very much like acne. It is usually localized upon the face and chest, and an experienced observer generally distinguishes it by its marked nodular infiltration and bluish appearance. It may develop into suppurating sores covered with crusts which resemble chancroids, and which persist in the resemblance even microscopically by exhibiting a marked overgrowth of epithelium.

OTHER CUTANEOUS MANIFESTATIONS IMPORTANT FROM THE DIAGNOSTIC STANDPOINT

Striæ.—The striæ caused by the stretching of the skin in edema resemble striæ gravidarum, and may persist for some time or even permanently after the edema has disappeared. (See p. 50.) Similar striæ may appear from the rapid accumulation or disappearance of the subcutaneous fat. Any cause which rapidly increases the size of the abdomen, such as pregnancy or the growth of tumors, may produce these striæ.

K. Ziegler's anatomic findings¹ indicate that the striæ arise from laceration of the elastic fibers of the reticular layer of the integument. These fibers undergo but a partial regeneration, so that the original condition is never reproduced.

Desquamation.—In cachexia and emaciation one frequently observes a diffuse, bran-like scaliness covering the skin of the trunk and extremities (pityriasis tabescentium). A characteristic lamellar desquamation of the skin, usually most conspicuous upon the palmar surfaces of the feet and hands, occurs after scarlet fever; a characteristic bran-like desquamation after measles; a more crust-like desquamation after small-pox; and a flaky desquamation after erysipelas.

Furunculosis, as a complication of some general disorder, such as diabetes, is of diagnostic interest to clinicians; otherwise, it concerns only dermatologists.

Scars.—The forms of various scars may be of some importance in considering the past history of a patient, *e. g.*, marks of vaccination, of

¹ Münch. med. Woch., 1905, No. 37.

small-pox, of furunculosis, of carbuncle, of lupus, of inguinal buboes, of tuberculous glands, and the bean-shaped scars of serpiginous syphilids. Unfortunately, even a slight scar does not always persist to show the site

Fig. 26.—Gouty tophi.

of the primary sore of syphilis. Surgical operations, various therapeutic measures, such as moxas, cautery, venesections, leeches, Baunscheidt's-

Fig. 27.—Crystals of sodium acid urate from a gouty tophus of the auricle.

mus, and epispastics, and wet-cupping leave behind permanent characteristic scars. They may be important in marking the dates of previous illness.

Gouty Tophi.—The occurrence of gouty tophi in the skin is of diagnostic importance. They are small swellings, somewhat resembling a milium or a small atheroma (wen) varying in size from that of a pin-head to that of a pea. They are most frequently found in the auricle, particularly in the region of the helix, where they are often connected with the cartilage. They usually present a white, transparent center, which upon incision discharges a creamy or chalky mass of sodium acid urate. When placed under the microscope, the crystalline character of the mass is revealed. (See Fig. 27.) It gives the murexid reaction for uric acid. (See Urinary Sediments.)

DETERMINATION OF THE BODY TEMPERATURE

Physicians in ancient times recognized as the principal symptom of fever an increase in the temperature of the blood. But the amount of fever was measured by the acceleration of the pulse. About the middle of the last century Traube, v. Bärensprung, and Wunderlich perfected the methods for taking the body temperature, considering it one of the essential points to be observed in an examination. Since their time the tendency has been to consider that an increase of the body temperature is the essential sign of fever.

The classic symptoms of fever include, in addition, weakness, malaise, anorexia, thirst, digestive and psychic disorders, rapid breathing, alteration in the amount of urinary excretion, and especially "consumption of the body."

Some, though not all, of the above-mentioned symptoms may be produced by an artificial overheating of the body. Certain of them, however, by no means run parallel to the increase of temperature; for sometimes, either with or without antipyretics, the temperature may drop without any especial improvement in the other symptoms. Hence, an increase of body temperature is the most important and constant accompaniment of what we call fever, and to-day the terms are used interchangeably. But still we must not neglect the associated phenomena of the febrile symptom-complex in determining the severity of an attack, because they are partly independent of the temperature, and are sometimes much more important than the amount of temperature increase.

Our conception of fever has been materially clarified by recent writers, and the modern view of this important symptom will be set forth in the following paragraphs.

THE NATURE OF FEVER AND THE PRINCIPLES UNDERLYING ITS ESTIMATION

According to Liebermeister's generally accepted theory, which Hildebrand, Stern, and others have tried to support by recent investigations, fever depends upon an "adjustment" of the temperature regulation to a higher degree in which heat-production and heat-dissipation, the two factors whose product equals the body temperature, are supposed to behave in an entirely different manner depending upon the case, but the end-result is the same, viz., increased body temperature. In the author's (unpublished) lecture upon fever he has proved that this theory is untenable and he has substituted a simpler conception which is more in accord with physiologic and clinical data. This conception will be fully treated in a monograph now in

preparation, but a brief sketch of its salient features may be inserted here. It is unquestionably convenient to regard fever and an increased body temperature as one and the same thing, but from a clinical standpoint this is not entirely satisfactory. Liebermeister's theory is based upon the supposition that there is a special center in the brain for the regulation of the temperature. The author wishes to emphasize particularly that this supposition is unnecessary, to say the least, and that its truth has not been demonstrated. The familiar experiments of Aronsohn and others with heat-stroke prove only that the body temperature may be controlled by the brain through vasomotor influence. This fact alone by no means justifies the supposition of a central regulation of temperature or of the existence of a heat center. Until proved incorrect the author would much prefer to believe that the regulation of the body temperature is a highly complicated process which may be influenced and disturbed by any of the organs, but chiefly by variations in the distribution of the blood. This assumption of a decentralization of heat-regulation explains why so many different conditions result in an increase of body-heat commonly known as fever, and also why factors working in opposition to these conditions may produce a subnormal temperature. The mechanism by which a febrile temperature is brought about seems to the author to be simply as follows: The internal organs are damaged by some toxic substance and there results, according to physiologic laws (acting also in inflammation and functional hyperemia), a vascular dilatation and an increase in the local circulation, in consequence of which the greater portion of the circulating blood is in the internal organs, while the skin, which serves for heat-dissipation, has less than its usual supply. The effect of this changed distribution of the blood is to diminish heat-dissipation, *i. e.*, there is a heat stasis, and, with Traube, the author sees in this the essential character of fever. Increased heat-production is frequently found in acute febrile conditions as an expression of toxic organic destruction, but this is not essential to fever, since there are fevers in which gaseous interchange is not increased. Moreover, the greatest possible increase in heat-production as seen in large eaters and in those doing heavy physical work is unable to raise the body temperature so long as heat-dissipation is sufficient. This idea that fever is due to diminished heat-dissipation seems to be the simplest possible one and one firmly supported by physiologic facts. To assume that fever is maintained by an alteration in the "regulation center," and that external cooling agencies do not easily reduce the fever is to misinterpret the facts in the case. The fact that cooling the surface of a febrile patient has little depressing influence upon the temperature is not due to the action of a regulating center, but rather to a failure in regulation in that the skin is insufficiently supplied with blood, and therefore external cooling cannot be effective. This conception is supported in every particular by clinical conditions. In the first place, it explains the manifold disturbances of function of the organs which accompany fever, only a portion of which can be attributed to the febrile elevation of temperature. Most of these disturbances of function are due to toxic substances and cause the febrile disturbance of the circulation so that the concomitant phenomena themselves will vary considerably in accord with the impaired functions of the viscera. As a consequence of the author's conception of fever as a circulatory disturbance it follows that there must be, to a certain extent, a "fever without fever," a latent fever, *i. e.*, a febrile disturbance of the circulation without an elevation of temperature. This previously inexplicable phenomenon, frequently observed in tuberculous patients (indicated by high pulse frequency, anorexia, etc., *i. e.*, febrile phenomena without elevation of temperature), is at once explained by the supposition that there exists in these cases the typical febrile circulatory disturbance or the increased circulation in the damaged internal viscera, but that, owing to diminished metabolism (anorexia), heat-production is so reduced that the internal temperature does not rise in spite of the diminished heat-dissipation. The occurrence of what the author has designated as "relative fever" is also at once explained by his theory. By relative fever, likewise frequently observed in tuberculous patients, we understand that the temperature does not exceed the usually accepted febrile limit (37.3° C. or 99.1° F. in the evening), but that the temperature is nevertheless higher than we would regard as normal from the constitutional peculiarities of the individual. It is well known that there are individuals whose normal temperature never reaches 37° C. (98.6° F.), and in whom an evening temperature of 37.2° C. (98.9° F.) is consequently to be regarded as febrile and is associated with general febrile phenomena. A further consequence of the author's conception is that fever limits are to be regarded as purely conventional and indefinite. The well-established clinical fact that a wider range in the daily temperature variations may indicate fever agrees very well with his conception and is a special instance of a "relative fever" in which the heat-stasis is shown only by the fact that the increase

in heat-production occurring physiologically during the day (see p. 74) augments the daily temperature variations as a result of the insufficient heat-dissipation.

Furthermore, the author's conception of fever suggests that the fever is purposeful and has a beneficial influence in that the altered circulatory conditions bring more blood to the damaged viscera, but there is absolutely no reason to regard the elevation of temperature in the same light. Such an elevation of the internal temperature due to lessened cutaneous circulation should be considered rather a by-product. This is what we should expect *a priori* from the physiologic adaptation to temperature in the normal subject, even if it had not been proved experimentally that the organism is directly damaged by overheating.

As far as the theory of antipyresis is concerned, the author's conception of fever leads him to believe that antipyresis is a valuable measure provided that the change it brings about in the circulatory conditions is not too violent, too abrupt, nor of too long duration, a conclusion supported by clinical experience. Antipyresis is also recognized as beneficial by the patient himself. From this belief important therapeutic deductions may be made as to the best methods of reducing fever, but their consideration cannot be taken up at this place.

In reference to "sthenic" and "asthenic" fever, see p. 148 et seq.

Before the use of thermometers physicians estimated the temperature by the sense of touch. Though generally this is a perfectly satisfactory method of telling whether or not fever is present, many mistakes may arise. The hand appreciates only the temperature of the skin. This does not always bear a direct relation to the internal temperature of the body or of the blood; because the skin temperature evidently depends not only upon the temperature of the blood, but also upon the amount of blood in the skin at a given time, as well as upon the conditions of heat radiation. For example, during a chill the cutaneous temperature is often diminished as a result of a contraction of the peripheral vessels, while the blood temperature, as shown by the thermometer, is increased. Conversely, the cutaneous temperature of perspiring patients seems increased, provided evaporation and subsequent cooling are prevented by their being wrapped up, because the skin contains an increased amount of blood. Yet the internal temperature need not be raised. These possible sources of error make it plain that thermometers are essential for the accurate determination of the temperature relations. Nevertheless, palpation of the skin is of some value in disclosing the condition of the cutaneous circulation. It is oftentimes accurate, provided that evaporation, chill, and profuse perspiration can be excluded. Perhaps the best place for such palpation, when the patient is in bed, is the back; for there the temperature must be nearly the same as that of the blood. In spite of a high temperature, the skin need not feel very hot to the physician's hand if the room temperature be low and the skin, as well as the blood itself, has been cooled by the surrounding air. This is a point especially to be remembered in considering the possibility of ambulatory typhoid.

THE THERMOMETER

The thermometer carried by practitioners is subdivided in England and America according to the Fahrenheit scale, from 95° to 115°, and on the continent, according to the Celsius scale, from 20° to 45°. To convert Fahrenheit into Celsius and vice versa:

$A^{\circ} \text{ Celsius} = (\frac{5}{9}a + 32)^{\circ} \text{ Fahrenheit, or}$

$A^{\circ} \text{ Fahrenheit} = (a - 32) \frac{9}{5}^{\circ} \text{ Celsius.}$

A variety of small clinical thermometers can be obtained in America and in England (perhaps the best are the English make). They are very

accurate, so that an explanation of the method of correcting and tabulating their errors is hardly necessary. [The one-minute Hick's maximum clinical thermometer, furnished with a prismatic lens to magnify the column of mercury, is perfectly satisfactory.—Ed.] The cylindrical is ordinarily more convenient than the old-fashioned spheric bulb. The so-called "maximum" thermometers in most common use to-day require vigorous shaking to push the mercury down below the normal point. Then the mercury remains at whatever height it may reach until shaken down again.

METHOD OF TAKING THE TEMPERATURE

The temperature is ordinarily taken by placing the bulb of the thermometer beneath the side of the tongue, and instructing the patient to keep the lips tightly closed during the necessary interval (one to five minutes). Temperatures taken in the mouth are influenced by the temperature of the external air and also by local heat-production on the part of the salivary glands. In some cases it may be necessary to obtain the temperature in the axilla, and, when there is any doubt, in the rectum or vagina. It is hardly necessary to caution a physician to be most careful in disinfecting the thermometer after each time it is used.

In many of the hospitals in Germany a large thermometer is employed. It is left in the axilla from fifteen to twenty minutes. With comatose, stupid, or violently delirious patients or with patients suffering from severe dyspnea or from nasal obstruction sufficient to impede breathing, the temperature must be taken in the rectum or vagina.

[The ordinary one-minute clinical thermometer is sufficiently accurate when used in the mouth, and absolutely so in the rectum.—Ed.]

In any case the temperature should be taken at least twice a day, and under many conditions every two to four hours. When the morning and evening temperatures are taken, the morning commonly represents the temperature between 7 and 9 o'clock, and the evening between 4 and 6 o'clock, which furnishes a practical maximum and minimum without disturbing the patient's sleep. (See pp. 74 and 76.) The temperature is ordinarily indicated upon temperature charts ruled either for every two hours or merely for morning and evening. The normal line is generally printed more deeply or in another color. (See Figs. 34 and 35 for a convenient method of indicating night and day temperatures.)

The temperature-curve alone sometimes suffices to make a diagnosis with considerable certainty; as, for instance, in typhoid fever, pneumonia, chronic tuberculosis, malaria, and suppurative processes. Even a single estimation of the temperature will often throw considerable light upon the diagnosis. Malingering may be excluded if there be decided fever.

THE NORMAL BODY TEMPERATURE

The normal temperature is 0.2° to 0.5° C. (0.4° – 1° F.) higher in the rectum or vagina than in the axilla. Von Bärensprung gives the following figures as the normal mean in the axilla at the various ages:

First 10 days.....	37.75° C. (99.95° F.).
Up to puberty.....	37.43° C. (99.37° F.).
15 to 20 years.....	37.19° C. (98.94° F.).
21 to 70 years.....	36.85° C. (98.33° F.).
80 years.....	37.26° C. (99.07° F.).

These figures have but a relative value, since they show simply the variations in body temperature for individuals of different ages. They are undoubtedly too high, evidently because of the employment of a defective thermometer.

These, of course, are the daily averages. The daily variation of temperature in a normal person is shown in Fig. 28. The minimum of temperature is observed in the first few hours after midnight; its first maximum is reached during the forenoon, generally between 9 and 10 o'clock; it falls again before the midday meal, rises and reaches a second, the proper maximum, some time between 5 and 8 o'clock in the evening; it then begins to fall until the first minimum is reached. The periodicity of the normal temperature-curve probably depends primarily upon variations in heat-production. The change from waking to sleeping undoubtedly also plays an important rôle, for there have been numerous examples of people accustomed to reversing the day, sleeping in the daytime and working in the night, in whom the temperature variation is reversed.¹

Fig. 28.—Daily curve of the normal body temperature (Liebermeister).

Food and physical exercise influence the temperature. Mountain-climbing, for example, has raised the temperature in normal individuals as high as 40° C. (104° F.). The marked elevations of temperature (as high as 40° C. (104° F.) reported by some observers are undoubted instances of true fever and are to be attributed to pathologic disturbances of internal organs, the muscles being chiefly responsible. The temperature of the external air has some effect upon the body temperature. Sometimes just before a thunder shower a slight rise has been noted in normal individuals. Liebermeister's chart shows that the daily variation amounts to 1° C. (1.8° F.), comparing the absolute maximum and minimum, but to not more than 0.5° C. (0.9° F.), comparing the morning temperature at 8 or 9 o'clock and the evening temperature at 5 o'clock. An evening temperature of 37.3° C. (99.14° F.) is within physiologic limits; although in many individuals, and particularly in consumptives, it would probably correspond to a rectal temperature of 38° C. (100.4° F.), and so indicate fever.

[Unless otherwise stated, these temperatures are mouth temperatures.—Ed.]

FEBRILE TEMPERATURES

Temperatures which exceed 37.3° C. (99.14° F.) are usually regarded as febrile. Wunderlich has computed the following fever scale:

- I. Normal temperatures, 37°-37.4° C. (98.6°-99.3° F.).¹
- II. Subfebrile temperatures, 37.4°-38° C. (99.3°-100.4° F.).²
- III. Febrile temperature:
 - (a) Slight fever, 38°-38.4° C. (100.4°-101.1° F.).
 - (b) Moderate fever, 38.5°-39° C. (101.3°-102.2° F.) in the morning to 39.5° C. (103.1° F.) in the evening.
 - (c) Considerable fever, up to 39.5° C. (103.1° F.) in the morning to 40.5° C. (104.9° F.) in the evening.
 - (d) High fever, above 39.5° C. (103.1° F.) in the morning and above 40.5° C. (104.9° F.) in the evening.

With our present conception of fever (see p. 70 et seq.) these gradations are of but little value. Disregarding the fact that the limit of the normal temperature in this table is at least 1° C. too high,³ since such sharp demarcations do not exist. According to the author's conception, this table possesses simply a conventional or terminologic value.

Hyperpyrexia.—Very unusual temperatures, 41° or 42° C. (105.8° or 107.6° F.) are spoken of as hyperpyrexia. Teale's case (injury to the spine and recovery) is the highest recorded temperature, 50° C. (122° F.). At the Insel Hospital, Berne, a patient with typhoid fever, who subsequently recovered, once exhibited a temperature of 45° C. (113° F.). Similar cases are quoted in literature as medical curiosities. A temperature above 42° C. (107.6° F.) is rare to-day, because we now have at our command more efficient means of combating fever.

In conjunction with Wunderlich's conventional grades of fever it will be well to recall what has previously been stated at p. 71 in reference to relative fever.

Stern has recently given to the term hyperpyrexia a general pathologic significance, limiting it to those cases in which the heat-regulating apparatus is insufficient, in contradistinction to febrile temperatures where the regulating apparatus is capable of preventing a further increase or an undue diminution. Hyperpyrexia includes, therefore, the excess of temperature added to fever by insufficient heat radiation. Such a differentiation is not compatible with the previously stated conception of fever. (See p. 70.)

PROGNOSTIC SIGNIFICANCE OF HIGH TEMPERATURES

Although a certain significance can be attributed to the height of the temperature, we must be very guarded in making the prognosis of a disease, and must not assume that every high fever is necessarily fatal. In general a typhoid fever with a high temperature-curve is more severe than one with a low range, and in the same patient an increase of temperature generally coincides with some more serious condition or with a complication. The bearing of a certain height of temperature upon the prognosis varies greatly in different diseases. In malarial fever, for example, the temperature may be extremely high without rendering the prognosis more serious; on the other hand, quite innocent throat affections in children are responsible for temperatures of 40° C. (104° F.) or more.

Unverricht⁴ has published a collection of abnormally high temperatures in which, nevertheless, recovery followed.

¹ This should be replaced by 37°-37.2° C. (98.6°-98.96° F.), as explained in the following paragraph.

² This should be replaced by 37.3°-38° C. (99.14°-100.4° F.), as explained in the following paragraph.

³ The author believes that the reason why the old boundary given as the upper-limit of normal temperature was too high, was largely because initial pulmonary tuberculosis was formerly overlooked and the symptoms of such patients were regarded as "neurasthenic," anemic, etc. This false dividing line has exerted a deleterious influence for years, for initial tuberculosis was, and still is, frequently unrecognized sufficiently early.

THE FEVER COURSE

DAILY VARIATIONS OF THE FEVER; THE FEBRILE TYPE

The daily course of temperature in any case of fever lasting one or more days is usually much the same as in healthy individuals. If the curve pictured in Fig. 28 were elevated one or two degrees throughout, it would correspond accurately enough to the daily variation of many a fever. But in numerous febrile diseases the maximum or minimum point may appear at a different time; for example, the maximum point may occur in the forenoon or at midday. Again, the daily variations may be much greater than in a normal individual, or in the morning the patient's temperature may be normal or subnormal and in the evening elevated two or more degrees. It is, therefore, evident that to obtain the accurate temperature of a patient with fever we must not be content with measuring the temperature at morning and night alone, but take it at regular, shorter periods, such as once in two hours or once in four hours. An irregular fever is often first discovered by taking the temperature at an unusual time; for example, late at night. A very good indication of the amount of fever is, of course, the patient's feelings; the sensation is not always one of heat, but rather that of general discomfort.

Various types are distinguished according to the variation of the fever during the day. In prolonged or *continued fevers* the daily oscillations rarely vary more than in a normal individual, *i. e.*, not more than 1° C. (1.8° F.). In *remittent fevers* the daily variation is more than 1° C. (1.8° F.). In *intermittent* or *interrupted fevers* the daily minimum is normal or below normal. Since malaria is now so commonly called intermittent fever, it is perhaps advisable to designate this type as *interrupted fever*.

COURSE OF FEVER FOR LONGER PERIODS; COURSE OF FEVER IN A RESTRICTED SENSE OF THE WORD; THE FEVER CURVE IN DIFFERENT DISEASES

The *fever type*, meaning more particularly the daily variations, is of less diagnostic importance than the so-called course of fever or *fever curve*, including a longer period of observation.

EPIHEMERAL VARIETIES OF FEVER (SINGLE-DAY FEVERS) (FEBRICULA.—ED.)

Ordinarily these are due either to well-known infections which run an abnormally rapid or abortive course, but whose nature is shown partly by the objective examination, partly by the prevalence of an epidemic of similar cases, or to slight infections of some unknown origin; or to temporary digestive disorders; or finally to some nervous influence, such as hysteria or mental excitement. Children, as is well known, exhibit a transitory rise of temperature from very insignificant causes. In the beginning of an ephemeral fever a diagnosis is almost impossible, so that the height that the temperature reaches will often cause apprehension.

Under this heading is included the fever which appears after *catheterization*, whose origin we do not perfectly understand, and the brief fever following *aseptic operations*. The latter is to be explained by purely psychic influences, such as anxiety as to the result of the operation; by the toxic action of the anesthetic, or of the antiseptics employed; and by the absorption of the relatively harmless secretion of the wound, etc. Where the consistence of the blood is altered by some therapeutic interference, such as transfusion of blood, of salt solution, or of colargol injections, we often observe fevers of similar slight import. In such cases

the origin may depend upon some slight infection or upon fermentative intoxication. In any case these rises of temperature are generally transitory and innocent.

Notwithstanding these numerous types of ephemeral fever no careful physician, in any febrile attack, will neglect a thorough search for some objective explanation or some evidence of infection.

FEVER CURVE OF CROUPOUS PNEUMONIA AND ERYSIPELAS; CRISIS AND LYSIS

There are a number of diseases with continued fever in which the course of the temperature is sufficiently characteristic to furnish the diagnosis. Croupous pneumonia is one of these. It is generally ushered in with a chill, and followed within a few hours by a rapid rise of temperature— 39° to 40° C. (102.2° – 104° F.)—although shortly before the chill the patient had apparently been feeling well. The fever persists with but slight variation for several days (five to nine days), and then subsides as rapidly as it developed, the drop usually being accompanied by a profuse perspira-

Fig. 29.—Temperature, pulse, and respiration curves in croupous pneumonia.

tion. This sudden drop in the temperature, so characteristic of pneumonia, is called the *crisis*. *Lysis*, in contradistinction, signifies a gradual drop of temperature during two or three days. The latter is rarely observed in croupous pneumonia, but very commonly in many other febrile diseases. A *protracted crisis* is a transitional type between the two. An *interrupted crisis* is a critical drop of temperature interrupted by a transitory rise. A *pseudocrisis* is one in which a critical fall is rapidly followed by a rise and persistence of the fever. A decided rise of temperature associated with a marked disturbance of the patient's general condition, the so-called *per-turbatio critica*, sometimes precedes the crisis. All of these conditions may be variously combined in pneumonia (Fig. 29). So far as the fever is concerned, erysipelas resembles it very closely.

THE COURSE OF TYPHOID FEVER

The temperature of typhoid fever is characterized by a gradual, stepladder-like onset, so that each evening it reaches a little higher point than the evening before. The *initial stage* lasts four to seven days; it is followed by a period of continued

high temperature without much of any diurnal variation, the so-called *fastigium* (seven to ten days); and then by a period of remittent fever, the *amphibolic stage*, in which the diurnal variations are very marked, often with a difference of several

Fig. 30.—Temperature, pulse, and respiration curve in typhoid fever (schematic).

degrees. This lasts five to ten days, and merges into the *defervescing stage*, which is as gradual as the initial rise. The chart (Fig. 30) shows this peculiar temperature curve better than we can describe it.

TEMPERATURE CURVE OF MALARIAL FEVER

The curve of malarial fever (Figs. 34 and 35) is characterized by a critical rise and fall of the temperature every two or three days, associated with the other symptoms of an acute disease. In typical cases the patient feels quite well during

the interval; the rise of temperature occurs very suddenly, is accompanied by a marked chill, and is followed later by a sudden drop and a profuse perspiration. The various types are named *quotidian*, *tertian*, and *quartan* fever. As a rule, in

* Fig. 33.—Temperature curve in small-pox.

malaria the attacks are repeated at exactly the same hour. Numerous exceptions do, however, occur; in the anticipating variety, the attack of fever appears a little earlier each day; in the postponing variety, a little later each day.

CURVE IN RECURRENT FEVER

As in malaria, so in *relapsing fever*, the temperature curve consists of a number of individual exacerbations. Each exacerbation and each interval, however, persists for several days in recurrent fever (Fig. 36). The relapses may be repeated several times, but finally become shorter and less severe, until complete defervescence takes place.

RELAPSES

In any acute infectious disease there may be a return of the specific symptoms, and especially of the fever, after convalescence has apparently begun, and all symptoms have been absent for some time. Such relapses are most common in typhoid. They should not, of course, be confused with the individual attacks in *febris recurrens*

Fig. 34.—Temperature in intermittent quotidian fever.

or malaria, nor with any complication of the original disease; as, *e. g.*, an otitis in measles or scarlet fever. By *recrudescence* is usually meant an intercurrent increase of temperature which resembles a relapse in that it is due to a lighting up of the original disease process and not to a complication, but which differs from a relapse in that it occurs before complete defervescence.

HECTIC FEVER

This is the typical fever of *chronic tuberculosis*. It generally persists a considerable length of time and is of a remittent or interrupted character, with sudden rises and falls. The minimum temperature is usually in the morning and the

maximum in the evening, or the opposite type may occur—inverted hectic fever.¹ A two-hour chart exhibits a very irregular course, with many slight rises and falls throughout the day.

Fig. 36.—Temperature in intermittent tertian antepontic.

Under hectic fever should also be considered that form of relative fever (see p. 71) which manifests itself by an increased range of the daily temperature without reaching the conventional fever limit. It is observed not only in tuberculosis, but also in digestive disturbances.

¹ The cause of this remarkable inversion has not yet been established. Factors which may be considered are: deficient expectoration during the night, increased heat-stasis from too many bed-clothes during the night, increased heat-production during the night from sleeplessness and excitement.

PUS OR SUPPURATIVE FEVER, IRREGULAR CHILLS IN PYEMIA, ULCERATIVE ENDOCARDITIS, AND GALL-STONES; CHILLS IN INFARCTIONS

Though often resembling the chart of hectic fever, that of suppuration is generally more irregular in the time and the degree of the exacerbations and remissions.

Days of Fever.

First apyrexia. First relapse. Second apyrexia.
Fig. 36.—Temperature of recurrent fever (Wunderlich).

In pyemia the fever frequently occurs in very intense paroxysms, accompanied by severe chills resembling those of malaria, except that

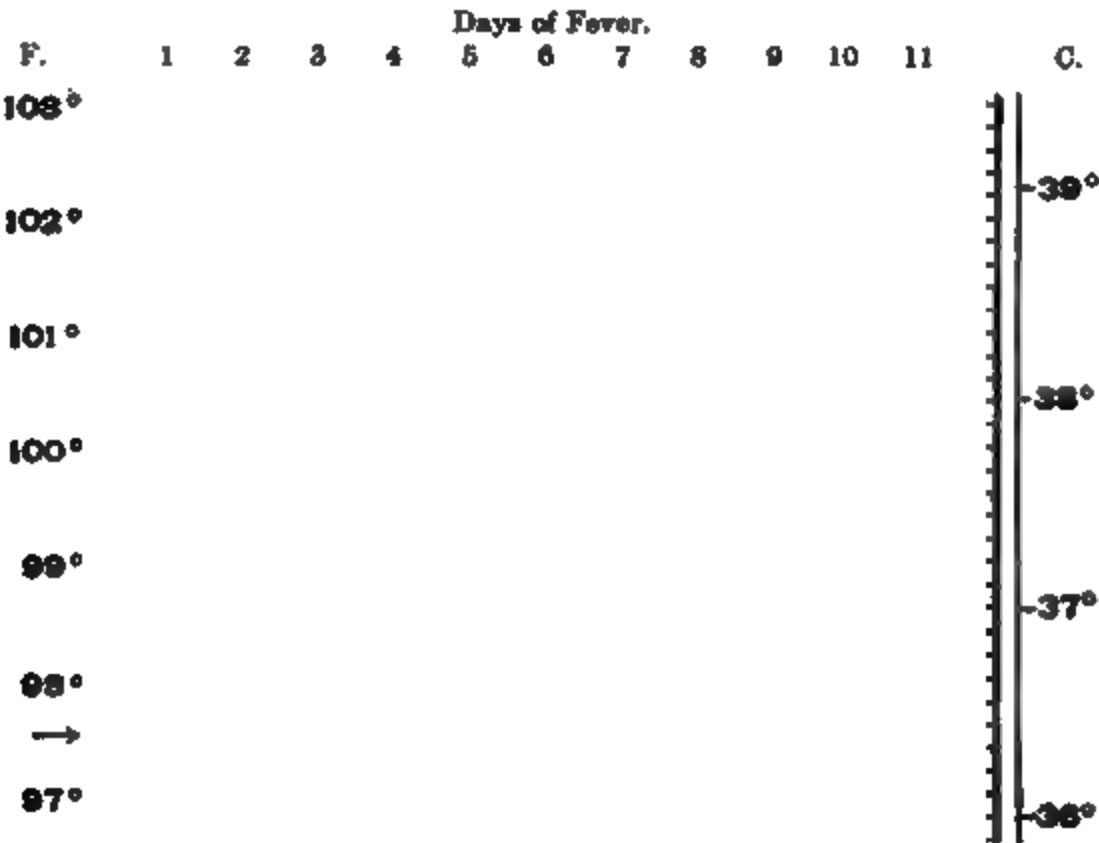

Fig. 37.—Hectic fever in phthisis.

they are more irregular. Closely related to these so-called erratic chills of pyemia are the chills which appear in ulcerative endocarditis and in

gall-stone affections. Non-purulent infarctions are associated with a similar, though less pronounced, chill.

ATYPICAL FEVER

In some diseases there is no type to the temperature course, so that, although the clinical picture is sufficiently constant, the temperature chart alone would furnish very little information of the nature of the disease. Examples are *diphtheria* and *septic processes*.

SUBNORMAL TEMPERATURES

These are quite as important clinically as febrile temperatures.

Wunderlich considers anything below 36.25°C . (95.25°F .) a sub-normal temperature.

Fig. 38.—Pulse, temperature, and respiration in collapse.

Marked depressions of temperature are noted:

1. In the prolonged action of intense cold.¹ A temperature of 27°C . (80.6°F .), as in a case of freezing, is not necessarily fatal.
2. Following a pronounced critical fall of temperature in fever. After the crisis in pneumonia the temperature often drops to 34° or 35°C . (93.2° or 95°F .).
3. In so-called "collapse," where there is a sudden fall in the temperature. This occurs in very sick patients (especially those with fever),

¹ Compare Glaser, "Ueber Vorkommen und Ursachen abnormaler niedriger Körpertemperaturen," Inaug. Diss., Bern, 1878; and Janssen-Quincke, "Ueber subnormale Körpertemperaturen," Deut. Arch. f. klin. Med., vol. liii, p. 247.

and is associated with marked weakness, numbness, rapid pulse, profuse perspiration, etc. The crisis in pneumonia is sometimes mistaken for a collapse. The pulse, however, in the latter is weak and rapid; whereas in the former it remains of good strength, and diminishes in frequency in proportion to the fall in the temperature. Collapse, though sometimes recovered from, is frequently an immediate precursor of death. The accompanying symptoms are usually attributed to cardiac weakness. Vasomotor inhibition may also be a factor.

4. Sometimes *after a severe hemorrhage*; in *chronic heart and lung diseases*, which lead to imperfect aëration of the blood (cyanosis), and therefore to insufficient oxidation in the various processes throughout the body; further, in *chronic wasting diseases* (carcinoma of the esophagus), where metabolism is reduced to a minimum; in *sclerema neonatorum*; and finally in *mental afflictions*, especially of the melancholic type.

Prolonged subnormal temperatures accompanying such conditions as are mentioned above always indicate a grave diminution of the metabolism or some equally serious disturbance of the heat regulation.

CHARACTER OF THE RESPIRATION

FREQUENCY OF RESPIRATION UNDER PHYSIOLOGIC CONDITIONS

Hutchinson considers the normal respiratory frequency in adults between 16 and 24, or about 1 to every 4 pulse-beats. Quetelet gives for the new-born an average of 44, for the five-year-old child 26, respirations to the minute.

It is a good plan to count the respirations while apparently feeling the pulse, because the patient's attention might otherwise modify the rate. For greater accuracy, the number of respirations should be counted during an entire minute.

Physical exertion will increase the rate of respiration; rest or sleep will diminish it somewhat. A stomach distended by food and drink increases the rapidity of the respiration because the diaphragm excursion is thereby somewhat limited, and also because the oxidation processes of the organism are considerably increased immediately after an abundant ingestion of food. Irritation of the skin may increase or diminish the rate of respiration. Psychic or sensory impressions, movements, clearing the throat, eating, drinking, or smoking will alter the rapidity of the respiration. Before considering that a certain rate of respiration is pathologic we must therefore bear in mind all these physiologic variations.

NORMAL TYPES OF BREATHING

The distention of the lungs with air takes place partly by means of raising the ribs and sternum and rotating the former outward and upward, and partly by depressing the diaphragm. Although in every-

body both these factors take part in the movement of inspiration, yet one or the other is apt to be more prominent, thus producing a more *costal* or a more *diaphragmatic* (*i. e.*, abdominal) type of breathing. Women commonly breathe costally; men, costo-abdominally. This difference, which seems to depend upon the formation of the chest, is naturally very suitable during pregnancy, when the diaphragmatic excursions are interfered with. A child's breathing is essentially costal.

PATHOLOGIC VARIATIONS IN THE TYPE OF RESPIRATION

Either the costal or the diaphragmatic element may be implicated and so alter the type of respiration.

Limitation of Diaphragmatic Breathing.—The excursions of the diaphragm may be impeded by some mechanical interference with its descent, *e. g.*, by a paralysis of its muscular structure; by an abnormal flattening of its vault (in certain types of emphysema); by painful breathing; by an increase in the abdominal contents, *i. e.*, pregnancy, meteorism, abdominal tumors, ascites. *Inflammation* in the vicinity of the diaphragm, *e. g.*, pleurisy, pericarditis, peritonitis, will limit the excursions of the diaphragm, partly on account of the pain and partly from a slight paralysis of its muscle-fibers (especially in diffuse peritonitis, on account of the disturbances in the circulation following the inflammation). Actual diaphragmatic paralysis occurs in *multiple neuritis*, in *progressive muscular atrophy*, etc. In any of the above instances the costal breathing may appear to be increased at the expense of the abdominal effort.

Limitation of Costal Breathing.—Costal respiration may be interfered with in a mechanical way by extensive ossification of the costal cartilages (ankylosis of the articulations of the ribs in arthritis deformans, etc.). Under such conditions the costal type in women and children and the costo-abdominal type in men may become purely abdominal.

DIAPHRAGM PHENOMENON AND ALLIED APPEARANCES (LITTEN'S SIGN)

Although it had been previously mentioned by Stokes and Gerhardt, Litten¹ deserves the credit for calling attention to this almost forgotten sign. He analyzed a series of cases, determined its practical significance, and named it the "diaphragm phenomenon" (Pl. 2). It consists of a horizontally placed shadow observed with inspiration near the lower pulmonary border, most constantly anterolaterally, but occasionally running in a ring around the whole chest. This shadow seems to slip downward, corresponding to the inspiratory descent of the pulmonary margin, as shown by percussion. It is very fittingly named, because, as a matter of fact, it is the most distinctly visible evidence of the depression of the diaphragm. Normally, the moving shadow begins above in the sixth intercostal space, descends with superficial inspiration one to one and one-half intercostal spaces, and with deep inspiration two to three spaces. It intersects the ribs at an acute angle. To show it most distinctly, the patient should lie as flat as possible (without extra support for his head) and with his feet toward the window, so that the region between the sixth rib and the costal margin is lighted obliquely. The observer should stand between the patient's feet and the window, with his eye at a distance of 3 or 4 feet from the lower thorax, the line of vision forming an angle of 45 degrees with the latter. Provided the patient breathes deeply and the light, although not necessarily strong, slants

¹ Deut. med. Woch., 1892, No. 13. "Das Zwerchfellphänomen und seine Bedeutung für die Praxis," Deutsche Aerztezeitung, 1895, No. 1. Verhandl. des Cong. f. inn. Med., 1895.

sufficiently, the phenomenon is generally plain. Even a candle light may be sufficient, but a very diffuse light is unfavorable. There is no corresponding expiratory sign. The flattening of the lower intercostal spaces from below upward during expiration is of quite different significance.

The explanation of Litten's sign is comparatively simple. As the diaphragm in its descent begins to peel off from the thorax and both widens and deepens the complementary pleural sinus, it exerts a suction upon the intercostal spaces just below the margin of the lung. This produces the shadow. It is evident that no analogous process will occur during expiration, because the elevation of the diaphragm is regulated only by the elastic retraction of the lung. In health, particularly in lean individuals, the diaphragm phenomenon is a nearly constant appearance. Marked development of fat or muscle or edema of the thoracic wall will prevent its appreciation, and even under perfectly physiologic conditions it may be sought for in vain. Its presence proves that at the particular place where it is observed, the diaphragm and the lung lie against the thoracic wall, both freely movable; its absence points to the opposite conclusion. Therefore it cannot be made out opposite pneumonic infiltrations nor in those places in pleurisy where the exudation is situated or where the lung is adherent to the chest, nor in hydrothorax or pneumothorax, etc. Litten has called attention to the fact that this sign is of great value in differentiating an empyema from a subphrenic abscess; it is absent in the former, but present in the latter.¹ Under some conditions the diaphragm phenomenon may facilitate a distinction between pneumothorax and diaphragmatic hernia. A broken or irregular shadow is said to point to partial adhesions of the diaphragm to the thoracic wall. The extent of the diaphragm phenomenon will furnish some idea as to the excursion of the lung in emphysema and phthisis. Paralysis of parts supplied by the phrenic nerve is associated with an absence of the diaphragm phenomenon. Since this sign is by no means absolutely constant in healthy individuals, it is evident that its absence upon one side alone is much more important than upon both sides.

We must be careful not to confuse the diaphragm phenomenon with two other conditions which exhibit shadows in the same area, viz., the visible depression of the lower ribs with expiration and the retraction of the lower intercostal spaces with inspiration.

The former, being expiratory, is easily differentiated from the diaphragm phenomenon; but the latter, being inspiratory, is more difficult to distinguish. The lower intercostal spaces situated along the attachment of the diaphragm are under a positive intra-abdominal pressure when the latter is in a position of expiration, whereas they are exposed to a negative intrathoracic pressure when the diaphragm is depressed by inspiration, and therefore they are retraced in the same way as the diaphragm. The physiologic retraction of the lower intercostal spaces as a whole will thus present a descending shadow easily to be confounded with the Litten sign, but a careful observation will detect the difference. The shadow of the Litten sign is linear, passing through the intercostal spaces as a line, while the shadow of the physiologic retraction of the intercostal spaces is more diffuse, each space, one after another, becoming shaded *in toto*. Very often also the descending character of the inspiratory retraction cannot be recognized at all, because the diaphragm in its contraction exerts a suction upon those intercostal spaces from which it has not yet separated. A further distinction is that an exactly opposite movement from below upward takes place during expiration, i. e., an expiratory bulging. This does not occur in the diaphragm phenomenon.

The depression in stenosis of the air-passages, and the essentially identical peripneumonic retraction, differ from this physiologic retraction in that the appearances are very much more marked in the former, affect the ribs as well, and are not confined to the intercostal spaces in the territory of the diaphragm.

In cases where the diaphragm phenomenon was not plainly recognized, the author has succeeded in bringing it out very plainly by faradic stimulation of the phrenic nerve. With sufficient current the diaphragm contraction follows so quickly and energetically that the phenomenon is often much plainer than with ordinary breathing. In this way we may bring out very plainly differences between the two sides.

¹ It is well, however, not to lay too much stress upon this statement, because, although its existence in the latter condition has been demonstrated, we can as yet scarcely be sure that the diaphragmatic movement is not sometimes impeded by a subphrenic abscess.

PLATE 2.

1

2

3

Diaphragm phenomenon (Litten's sign), from a patient with fibroid phthisis of left lung (New York City Hospital). The linear shadow has been emphasized in the reproduction of the photographs.

1. *Full Expiration*.—Note the height of the shadow and the slight concavity of the abdomen corresponding to the respiratory phase.

2. *Medium Inspiration*.—Note the descent of the linear shadow and the slight change of contour of abdomen corresponding to the respiratory phase.

3. *Deep Inspiration*.—Note the further descent of the linear shadow and the rigid abdomen corresponding to the respiratory phase.

Although the artist has intensified the shadow in the reproduction, the excursion of the right lung and right side of the diaphragm were so pronounced in this patient that the distance between the shadows in the extreme positions of respiration was greater than has been represented. The patient's left lung was practically useless, hence the abnormal extent of the right lung's excursion.

ASYMMETRIC RESPIRATION AND PATHOLOGIC INSPIRATORY RETRACTION OF THE CHEST

An obstruction to respiration which affects but one lung will cause asymmetric breathing; the diseased side will make a less extensive excursion and will also lag somewhat behind the healthy side. The conditions which may give rise to such a unilateral limitation of breathing are: the various types of pulmonary consolidation (pneumonia, phthisis, tumors); pleurisy with effusion or pleurisy merely with the formation of fibrous bands and tough adhesions; and pericarditis with effusion. Asymmetric respiratory excursions may be appreciated by inspection, but they will oftentimes be much better appreciated by palpation. With one hand placed upon each side, the examiner can at the same time appreciate an asymmetry of the chest contour. The chest, half of whose mobility is diminished, may be either expanded or contracted, as explained upon p. 34 et seq.

Compare p. 93 et seq. for the occurrence of inspiratory retraction in the jugulum (suprasternal fossa), epigastrium, and flanks with stenosis of the upper air-passages.

But without any stenosis similar local retractions occur over parts of the lung area where the normal inspiratory distention of the lung is prevented by atelectasis or by consolidation. This retraction, especially when it occurs quickly and violently (as with dyspnea), is due to the variation in the inspiratory negative pressure within the interior of the chest, which draws in the more expansile portions of the lung along with the overlying portions of the chest-wall under the influence of the external atmospheric pressure. We see this particularly well marked in the catarrhal pneumonia of children, whose soft and more flexible chests favor the retraction. It is called a "*peripneumonic retraction*" or a "*peripneumonic groove*." It is generally situated in the lateral and anterior region of the chest along the lower lung border, even when the pneumonia is, as usual, situated in the back. This probably depends upon the fact that the inflexible consolidation located in the back interferes mechanically to a certain extent with the excursions of the lung margins at the sides and in the front, and that the anterior and lateral portions of the chest are especially flexible. Peripneumonic retractions are, however, sometimes observed posteriorly, near the inferior pulmonary margin. The direct pull of the diaphragm, just as in stenosis of the upper air-passages, may, in addition to these mechanical factors, help to create a peripneumonic depression. (See p. 94.) The epigastrium and the jugulum, too, may be retracted in a similar way in pneumonia, so that in small children the diagnosis of croup is not infrequently suggested. The inspiratory stridor and hoarseness of the voice and of the cough in the latter ordinarily facilitate a distinction. Peripneumonic retraction must not be confounded with the normal inspiratory depression of the lower intercostal spaces, the explanation and differentiation of which have been discussed upon p. 86 et seq. In pneumothorax also the author has seen marked retraction of the lower portion of the thorax, doubtless due to direct traction by the diaphragm.

D. Gerhardt¹ has called attention to another cause of inspiratory retraction of the lower thoracic margin. Besides the diaphragm's well-known effect upon the

¹ Zeit. f. klin. Med., 1896, vol. xxx, Nos. 1 and 2.

inferior surface of the lung, Duchenne demonstrated that, by resting on the abdominal contents and moving over the parts contained in its vault, as over a roller, it has in inspiration the action of lifting the margin of the thorax. If this decided elevation of the lower ribs be prevented by immobility of the costal articulations or by the horizontal position of the ribs, as in some emphysematous chests, or by the lack of any firm point of attachment of the abdominal contents in enteroptosis, then during inspiration the contraction of the diaphragm will depress the chest-wall inward.

ABNORMALITIES IN FREQUENCY AND RHYTHM OF THE RESPIRATION (not Including Dyspnea)

Alterations in the frequency of respiration depend, for the most part, upon difficulties of pulmonary aëration or upon increased demands upon the lung, and will therefore be considered and explained with the symptom-complex of dyspnea in the following chapter. Only in very rare instances are changes in the frequency of breathing independent of dyspnea.

To this group belongs the diminution of respiratory frequency (oligopnea) found in certain unconscious states, especially in severe brain affections (meningitis, hemorrhage, or in tumors of the brain); uremia; diabetic coma; severe infections; some cases of poisoning, and in a similar way in the final agony. Irregularity of the respiration may be noted as well in any one of these conditions. Unquestionably these disturbances are distinctly dependent upon an alteration in the function of the respiratory center.

Either one of two very characteristic types of pathologic breathing, each one associated with a change in the rhythm, and arising under exactly similar conditions, may occur instead of the slowed respiration just mentioned. These are the so-called Biot's or meningeal and the Cheyne-Stokes respiration.

Biot's respiration, especially common in meningitis, may also occur in other cerebral disorders and in other grave general conditions. It is characterized by very decided pauses in the breathing, which last from several seconds to half a minute or longer. They are more or less periodic, but at times are irregularly repeated. It is a phenomenon of grave prognostic significance.

Cheyne-Stokes respiration is characterized by similar long pauses in the breathing. It differs, however, from the above by the fact that the breathing begins very slowly and superficially after the pause, gradually increases in depth and intensity to a maximum, diminishes again, and finally stops entirely, thus producing another respiratory pause. It is, therefore, a distinctly periodic type of respiration. It occurs under similar conditions to the Biot's meningeal respiration, especially in grave affections of the brain, of the respiratory and of the circulatory organs, and quite frequently in arteriosclerosis and chronic nephritis. Although more frequently observed in the unconscious, it is not uncommon even when consciousness is maintained, especially in patients with chronic respiratory or circulatory disorders. In these affections consciousness oftentimes oscillates with the respiration, is periodically obliterated during the pause, and returns again when respiration is resumed. There are other phenomena more or less characteristic. During the pause in the breathing the rate of the pulse may be decidedly slowed, its tension may be altered, and the pupils may be contracted.

Very often, though by no means always, patients have a subjective sense of dyspnea during the period of increasing respiration; and if unconscious during the pause, they are awakened, as they express it, by a sensation of suffocation or dyspnea. Cyanosis usually accompanies the onset of the dyspnea, and it may sometimes even increase with the augmentation of the breathing. With some patients Cheyne-Stokes respiration occurs only during sleep. Medicinal doses of morphin usually intensify the phenomenon and may even originate the condition. Generally speaking, the prognostic significance is very grave, although not invariably fatal. According to the severity of the causal condition, the symptom is either transitory, or else one directly preceding death. Only in cardiac or renal disease has it ever been observed to persist for some months.

The explanation of Cheyne-Stokes respiration is still not wholly agreed upon. It is indisputable that, like meningeal breathing, it depends upon a diminished excitability of the respiratory center. This seems to be the only part of the explanation beyond a doubt. Traube's original theory assumed that the symptom arises when the excitability of the respiratory center is so decidedly diminished by the insufficient supply of oxidized blood resulting from the circulatory disturbance that, at a certain moment coinciding with the first breathing pause, there is no longer a sufficient physiologic stimulus to arouse the respiratory movements. With the cessation of respiration the blood becomes still more decidedly venous. This irritates the respiratory center intensely, so that, despite its diminished susceptibility, breathing begins again. This in turn diminishes the venous character of the blood, and the breathing gradually becomes weaker in proportion to the oxidation of the blood.

Traube's explanation does not make it very clear why the breathing increases gradually nor why the second respiration is stronger and deeper than the first. For as soon as breathing begins, the venous character of the blood must immediately lessen the respiratory center's irritation, and so the second respiration should be weaker. Traube explains that the first breath is so diminutive that it cannot affect the venous character of the blood, and so cannot lessen the irritation to the respiratory center; but that, on the contrary, the irritation increases despite the return of breathing, until it—the irritation—reaches a maximum. Such a hypothesis will explain the peculiarity that the patient appears most cyanotic and complains most of the subjective sensation of dyspnea during the period of increasing respiration. Another objection to Traube's explanation is that, after an improved supply of oxygenated blood has once restored the respiratory center's normal excitability, there is no apparent reason for the breathing fading away again. If we believe, with Traube, that asphyxia of the respiratory center is the sole cause of its diminished excitability, the objection cannot be answered. If, however, we regard the diminished excitability as entirely or partially independent of the asphyxia and more self-dependent, the objection loses its force. Evidently, then, if the blood be better aerated, the intense irritant to the respiratory center will be removed, although the latter's sensibility has not been improved. Hence, the breathing will gradually diminish in frequency in proportion to the improvement in the oxidation of the blood.

With these modifications, Traube's theory seems plausible enough. Partly on account of the difficulties mentioned above, numerous other

explanations of Cheyne-Stokes respiration have been advanced. We will mention only two of these which are the most generally known, viz., Filehne's and Rosenbach's.

Filehne's hypothesis, beginning with the pause in respiration, assumes that the venous condition of the blood irritates the vasomotor centers and so produces a spasm of the cerebral vessels. Therefore the respiratory center, whose irritability has already been reduced, becomes anemic. This anemia acts as a further irritant to respiration. As soon as the breathing has again oxygenated the blood sufficiently, the vascular spasm vanishes, but the respiratory stimulus is not sufficient to continue the breathing, hence the pause reappears. Filehne's theory is more complicated than Traube's; the same objections apply to it; and more accurate investigations seem to have disproved completely any such relationship between the vasomotor center and Cheyne-Stokes breathing.

Rosenbach maintains that the periodicity of this type of breathing results simply from an abnormal exhaustibility of the respiratory center (not to be confused with diminished irritability). The center is active for a time, works against a gradually increasing difficulty, finally stops entirely, and begins its activity again only after the pause has to some extent recuperated its powers. It seems doubtful whether we can assume that such recuperation of the respiratory center occurs during the breathing pause, while the respiratory irritant persists. The laws of fatigue in the central nervous system are, however, so imperfectly understood that this objection to Rosenbach's explanation is not sufficient to make us reject it entirely. At all events it has the advantage of depending upon the same law that applies to the other organs—that periodic activity usually arises as a result of fatigue.

Most types of increased respiratory frequency (polypnea) depend upon an increased demand on the respiratory activity, and will therefore be discussed in the following section on Dyspnea. We should, however, mention the fact that increased frequency of breathing may arise from purely nervous causes, *e. g.*, in hysterical people and in certain cases of cerebral disease.

DYSPNEA

The term dyspnea applies to a large group of variations in respiratory activity, which, in spite of considerable diversity in detail, have this in common, that they serve to promote the object of breathing, *i. e.*, the proper oxidation of the blood, despite all kinds of obstacles. On this account the breathing of dyspnea is generally increased in frequency or in depth. The obstructions to breathing are, however, sometimes insurmountable, so that neither a frequent nor a deep type of breathing is possible, *e. g.*, in marked stenosis of the air-passages. Therefore increased breathing must not be considered absolutely the essential feature of dyspnea. The only definition which will apply clinically to all cases is that dyspnea is an increased respiratory exertion produced by obstruction to breathing or by increased demands upon the blood-oxidizing process. This does not coincide with the explanation frequently given, that dyspnea is identical with quickened breathing, which is unquestionably inaccurate from the clinical standpoint, for not every case of quickened respiration is dyspneal nor is the breathing quickened in every case of dyspnea. As we shall see, there are

types of dyspnea with quickened and others with retarded respiration. To conform with the definition cited above and to avoid any misunderstanding, it is advisable to apply the terms *polypnea* to quickened and *oligopnea* to retarded breathing.

The word dyspnea is, however, employed in still another sense, to express the subjective sensation of oppressed breathing experienced by patients with objective dyspnea. Ordinarily, subjective and objective dyspnea go hand in hand; but exceptions do occur. For under certain conditions, despite the presence of some obstruction which is responsible for an objective dyspnea, breathing may continue so satisfactorily that the patient does not experience any shortness of breath, because, owing to the modification of the respiratory movement, the aëration of the blood is accomplished as completely as ever. Again, despite a very pronounced objective dyspnea which is by no means adequate for blood aëration, as evidenced by the accompanying cyanosis, a patient may have become so accustomed to it (see p. 102) or his sensorium may be so benumbed that he has no appreciation of subjective dyspnea. It is a very benevolent provision of nature that in the death agony, where the breathing is difficult, the brain becomes, as it were, so narcotized by the carbon dioxid intoxication that it no longer appreciates the sensation of the struggle for breath. Conversely, the objective dyspnea may be almost or entirely overshadowed by the intense "air-hunger." Examples are the so-called "precordial terror" of melancholiacs, which, because the individual locates the sense of anxiety in the chest, we prefer to consider as a subjective dyspnea which is purely cerebral. Again, some nervously organized individuals will complain of a transitory desire to draw an extra deep breath; they have the sensation of dyspnea without any evidence of obstructed breathing. In other words, it is a purely cerebral phenomenon, of which they instinctively try to rid themselves by taking a long breath.

Hence it is important to differentiate sharply between objective dyspnea, *i. e.*, difficult and hence modified breathing, on the one hand, and subjective dyspnea, or the sensation of lack of air, on the other. Sometimes breathing modified by dyspnea is accompanied by subjective dyspnea, but at other times this is not the case.

Cyanosis, like subjective dyspnea, is not always proportional to the degree of objective dyspnea, for in one case the objective dyspnea may be effective in regulating the proper aëration of the blood and in bringing conditions back more or less to a normal standpoint, whereas in other cases this is not possible for the organism.

The occurrence of decided objective dyspnea without cyanosis is a clinical proof that the intensity of the respiratory movement does not depend exclusively upon the grade of aëration of the blood, but may be produced directly by some obstruction to breathing without the appearance of cyanosis. A similar proof is furnished by the dyspnea which follows physical exertion. This in no way depends upon an excess of carbon dioxid nor upon a deficiency of oxygen in the blood so long as the breathing and the circulation remain sufficient.

To aërate the blood properly under adverse circumstances the organism avails itself of an increase either in the frequency or in the depth of the respiration. With an increase in the depth of the individual breaths, the frequency may be either accelerated, normal, or slowed. There are, therefore, various types of dyspnea, but generally we find

that it modifies the normal breathing in that way which seems best adapted to meet the existing deficiencies.

In the following we shall characterize the kinds of objective dyspnea occurring in different diseases.

VARIOUS TYPES OF DYSPNEA

1. Dyspnea Caused by Painful Breathing.—Patients are not infrequently prevented from drawing a deep breath on account of the pain associated with each respiratory movement in certain pulmonary, and especially pleural, disorders, in affections of the intercostal muscles (rheumatism, trichinosis) and of the diaphragm and its vicinity (peritonitis). The breathing then becomes superficial, and to satisfy the demand, more frequent—in other words, dyspnea results. In this instance the obstruction is functional, not mechanical.¹

2. Dyspnea Due to a Diminution in the Breathing Surface of the Lung or to a Mechanical Limitation of the Respiratory Excursions of the Lung.—The two factors ordinarily occur together. Under this heading are included all affections of the pulmonary parenchyma which lead to a diminution of the air content of the lung, *i. e.*, all sorts of pulmonary consolidation, as well as pulmonary edema; all conditions which limit the capacity of the thorax, such as pleuritic effusions, pneumothorax, intrathoracic tumors; lateral curvature, upward displacement of the diaphragm; further, all conditions which decrease the respiratory excursions, such as brown induration and emphysema (with regard to emphysema, see p. 97 et seq.), as well as paralyses and spasms of the respiratory muscles.

In any of the above conditions each breath aërates the lung less efficiently than normally, with a resulting dyspnea and increased frequency of respiration. Under some conditions the demand for air will be completely satisfied, so that in spite of the interference with respiration neither cyanosis nor any subjective sense of dyspnea ensues. Under other conditions the compensation is not always complete, especially when any increased demand for air arises, so that physical exertion will occasion cyanosis and a subjective sense of dyspnea.

If such an interference with breathing be unilateral, *e. g.*, consolidation or a pleuritic exudation, the dyspnea can be partially compensated by deeper breathing of the healthy side (vicarious respiration), as well as by the increased frequency of respiration.

(See p. 87 et seq. concerning local depressions of the thorax in this variety of respiratory interference.)

3. Dyspnea Due to General Circulatory Disturbances.—Non-compensated valvular lesions may be regarded as a type. Here the chief factor is the stasis or congestion, *i. e.*, the circulation is slowed and the blood accumulates in the veins, whether the difficulty affects the left, right, or both sides of the heart. As a consequence of the retarded current the different organs receive less arterial blood in a certain time and retain more venous blood; and since the respiratory center is also affected by this disturbance, more rapid and deeper breathing results.

The conditions become more complicated when the circulatory trouble originates in the left heart, because the congestion then includes

[¹ A type of dyspnea associated with a remarkable slowing of the respiration is sometimes observed in pneumonia when the accompanying pleurisy excites intense pain with each respiration.—ED.]

not only the general systemic veins, but also the pulmonary veins, thus adding another cause for dyspnea—namely, a marked distention of the pulmonary capillaries with blood. It was formerly assumed that this dilatation of the alveolar vessels impaired respiration by diminishing the amount of air in the lung. But this conception was shown to be incorrect by von Basch's experimental investigations upon pulmonary congestion, for he proved, on the contrary, that the lung overdistended with blood contains more air because the distention of the alveolar vessels also increases the circumference of the alveoli. Nevertheless, the process in question does impair respiration, because the lung, stiffened by the distention with blood, becomes more and more permanently fixed in the position of inspiration and expands but little. Pulmonary rigidity acts as a direct impediment to breathing (category 2) and increases the respiratory rate. If it be persistent, its effect is intensified by the formation of the so-called "brown induration."

In opposition to this mechanical theory of pulmonary rigidity we would emphasize the work of Krause, who found that, in spite of the engorgement of the lung, each respiratory excursion may even be increased, *i. e.*, the breathing may be deepened. In this case the author believes that the dyspnea is to be explained not by pulmonary rigidity, but by the fact that the respiratory surface of the dilated pulmonary vessels is relatively decreased in comparison with their contents.

When the lung is affected paroxysmally by pronounced engorgement with blood and rigidity, in disturbances of cardiac activity, the resulting attacks are named "cardiac asthma." This term is often wrongly applied to any kind of dyspnea which appears in heart disease. These paroxysms of cardiac asthma are brought on sometimes by exertion, sometimes by increased flow of blood to the lung in the recumbent posture, sometimes by altered innervation at the moment of falling asleep, and sometimes by entirely unknown causes.

Pulmonary rigidity and brown induration arise in mitral diseases, especially when compensation is good, *i. e.*, when the right ventricle does its work well. For this reason patients with a mitral lesion, despite good compensation, experience dyspnea, even with very moderate exertion.

As a further cause of dyspnea may be added the *bronchial catarrh* that almost always accompanies circulatory disorders.

4. Dyspnea Dependent Upon Obstruction of the Upper Air-passages.—Any obstruction in the large upper air-passages makes breathing difficult because it furnishes a resistance to the entrance of air and to the inspiratory pull of the respiratory musculature. The latter must therefore perform more work. It is evident that under these circumstances an increase in the rate of breathing would be not only very difficult, but also of little avail, while, on the other hand, simple reflection shows that slowed breathing would more readily overcome the obstruction. But to supply the requisite amount of oxygen the breathing must be deeper as well. And this is sometimes observed to be the method which patients adopt to overcome obstruction in the larger air-passages, but only when there is sufficient inspiratory power to overcome entirely the impediment in breathing, for by this method the lung is just as well ventilated in the unit of time as is the case under normal conditions. Lacking such power, the economy is obliged to depend more and more upon the less efficient means of increasing the frequency of the breath-

ing, which, of course, becomes superficial; but that it is always suited to the particular kind of mechanical obstruction is shown by the fact that the increased frequency is slight in comparison with the extent of the respiratory obstruction, for too frequent breathing would be of no avail. This peculiar type may be termed *dyspnea with a tendency to slowed breathing*. The frequency or the depth of the breathing preponderates, depending upon the relation between the stenosis and the respiratory power. This type is observed in stenosis of the pharynx from swelling of the tonsils; in retropharyngeal abscess; in true croup and pseudocroup; in edema and in spasms of the glottis; in paralysis of the abductors of the vocal cords; in stenosis of the larynx or trachea from tumors or foreign bodies; in obstruction of the trachea from external compression (goiter, aneurysm, etc.). If the stenosis be situated in one of the main bronchi, it will depend again upon the degree of obstruction whether the dyspnea is combined with slowed or accelerated breathing. If the lung upon the affected side can still be made use of, the dyspnea will be of the former type; but if the healthy lung must do almost all the work, the breathing will be rapid. In either case the economy selects the more advantageous method. Thus, in all the conditions in question the demand for air will be supplied and the subjective dyspnea and cyanosis avoided, unless, of course, the obstruction is too great.

When the obstruction in the upper air-passages is very considerable, and when, despite the changes in respiration resulting from the dyspnea, the lung can no longer completely fill itself with air again, the chest "pumps empty," so to speak. During inspiration an abnormally rarefied space is found in the lung, and the lateral flexible portions of the chest-wall, the epigastrium, the supraclavicular fossæ, and the suprasternal notch (jugulum) sink in under the influence of the external atmospheric pressure.

There is another cause for depression of the lower lateral chest regions in this form of dyspnea. As a result of the empty pumping, the vault of the diaphragm is not depressed with inspiration, but may even be sucked upward. Besides, as a result of the stenosis, the ribs cannot be lifted up by the diaphragmatic action (described by Duchenne, p. 88), and so the contraction of the diaphragm practically accomplishes nothing but drawing in its points of attachment to the ribs. This pathologic retraction of the lower lateral portion of the entire chest-wall must not be confounded with the purely physiologic retraction of the lower intercostal spaces in inspiration. (See p. 86.) The differentiation is easy enough. In the latter only the lower intercostal spaces along the line of the diaphragm are affected, and there is never any retraction of the ribs nor of the epigastrium. The retraction of stenosis is observed most distinctly in children because their chests are very flexible. It is very common in croup.

A peculiar stridor or a sort of whistling, due to the passage of air through a narrowed place, is a most characteristic accompaniment of dyspnea caused by stenosis of the upper air-passages. It is ordinarily heard much more distinctly with inspiration than with expiration. In laryngeal croup the stridor is due to the membrane covering the vocal cords. The inspiratory accentuation of the stridor is explained by assuming that, in spite of the inspiratory opening of the glottis, the vocal cords are not materially separated, and that, as a result of their slanting,

roof-like position, they are approximated still more closely, valve fashion, by the pneumatic tug of inspiration. Hence, the obstacle to inspiration is greater than to expiration. This explanation is probably correct for cases of laryngeal croup. Nevertheless, the same inspiratory increase of stridor is observed in other types of stenosis of the upper air-passages, where we cannot assume the result of any such valve-like effect in the larynx, *e. g.*, from obstruction either above or below the larynx (retropharyngeal abscess, goiter, etc.). The probable explanation of such cases is that the obstruction prevents the free ingress of air during the inspiratory effort at a moment when suction is exerted upon the surrounding parts by the external atmospheric pressure, so that the trachea is constricted below the sternum (inspiratory retraction of the jugulum, suprasternal notch). Therefore, any obstruction in the upper air-passages, even if not actually located in the larynx, acts much more effectually during inspiration than during expiration. In other words, the dyspnea is essentially inspiratory. Another factor may influence this inspiratory accentuation of the stridor. The velocity of the air-current in inspiration is much greater than in expiration, which is passive, depending upon the elasticity of the lungs and the thorax. The importance of this factor is shown by the fact that, as soon as patients with stenosis of the upper air-passages experience a sufficient increase in the respiratory obstruction to necessitate their employing the help of abdominal pressure, the expiratory stridor will become more marked, and may even outweigh the inspiratory stridor.

5. Dyspnea in Bronchitis.—The types of bronchitis which usually lead to dyspnea are chiefly those affecting the smaller bronchi. The dyspnea is caused by the stenosis of the bronchial lumen, due to swelling of the mucous membrane and to secretion. The stenosis affects so many places that ordinary breathing is insufficient and dyspnea arises.

This type of dyspnea varies with the conditions which prevail. If the stenosis affect only a small number of bronchi, simple increase of the breathing rate will usually overcome the difficulty. The stenosed areas are not benefited much by this method, but the uninvolved portions receive more air, and so the effect of the disturbance is compensated. This type of dyspnea then comes under our second heading. If the stenosis affect a large number of bronchi, the breathing varies according to whether the bronchial closure is quite complete and insurmountable, as in *capillary bronchitis* proper, or whether it is incomplete and still conquerable by the respiratory effort, as in *diffuse dry bronchitis of the medium-sized tubes*. In the former variety, of which capillary bronchitis is a type, the chief effect is again merely a diminution of the breathing surface, so that, as before, dyspnea with rapid respiration results. This, of course, only assists bronchial areas which still remain patent. In the second type, however, where we suppose that most if not all of the medium-sized bronchi are stenosed, although only moderately so (the so-called stenosing bronchitis in a more restricted sense), the respiratory effort must attempt to get a sufficient quantity of air through the constricted areas into the pulmonary tissue proper. This can generally be best accomplished by an abnormally deep respiration, very much as in stenosis of the upper air-passages, especially of the larynx. And just as in these cases, the respiratory accommodation and the frequency of the individual efforts will vary according to the amount of

obstruction as compared with the respiratory force available. In rare instances even a slowing of respiration may result. More frequently, however, we merely observe a certain tendency to retardation, in that the increase in rate does not correspond to the degree of constriction, and this increase is comparatively slight as contrasted with the amount of subjective dyspnea and cyanosis. The passage of air through these constricted areas is often associated here, as well, with a stridor, *i. e.*, a stenotic noise which may perhaps be heard at a considerable distance from the patient. This type of dyspnea in bronchitis presents, therefore, a prolongation of expiration and stridor, chiefly expiratory, and so can be distinguished from the other retarded type of laryngeal dyspnea, where expiration is of normal length and the stridor is chiefly inspiratory.

These two points of distinction, which are responsible for the application of the name expiratory to this type of dyspnea, require some further explanation. The prolongation of expiration is easily understood, because even under normal conditions expiration is longer than inspiration, and, of course, the increased resistance caused by the bronchial stenosis must be felt more during expiration, especially since the excitation of dyspnea produces, first of all, marked increase of the inspiratory power. To be sure, if the dyspnea be pronounced, the expiratory exertion must also be increased by the participation of abdominal pressure in the expiratory act, so that the lungs will then be emptied somewhat more quickly by the active expiratory compression of the thoracic contents than by the sole influence of elasticity. This extra abdominal pressure, however, will also compress the small bronchi still more; hence the prolongation of expiration as compared with inspiration, and the increase of expiratory stridor. Increased expiratory stridor may be present without the participation of abdominal pressure. For if the elastic retraction of the lung be interfered with by stenoses in the bronchi, the latter will be still more compressed by this elastic expiratory movement, just as by abdominal pressure. Hence, abdominal pressure is not absolutely necessary to account for the increased expiratory stridor. This compressing effect of expiration upon the finer bronchi is proved by the observation of the expiratory dyspnea in pneumothorax. (See p. 101.) All sorts of intermediate types occur between this type of retarded breathing with prolonged expiration and expiratory stridor, on the one hand, and the type in which the breathing is simply increased in frequency on the other. These types will vary according to the preponderance of bronchial stenosis or of the available respiratory power.

6. Dyspnea in Bronchial Asthma.—Bronchial asthma leads to a form of dyspnea with expiratory stridor, a so-called *expiratory dyspnea*, which differs from the expiratory dyspnea of stenosing bronchitis (see above) only by its occurrence in sharply circumscribed exacerbations or attacks. If the modern conception that bronchial asthma is due to a spasm of the bronchial muscles leading to a stenosis of the finer bronchi be true, the conditions correspond entirely with those in the last-mentioned form of bronchitis with diffuse moderate stenosis of the bronchi. This will apply so much the more if we regard asthma as a secretory neurosis associated with the production of viscid mucus. However, the author regards both these explanations of bronchial asthma as hypothetic and improbable, and for years has taught in his

clinic that the nervous element, undeniably responsible for the occurrence of attacks of bronchial asthma, is to be found simply in an increased irritability of the respiratory center.

Under all conditions a stenosing bronchitis is always present in bronchial asthma, and when the irritability of the respiratory center is increased from any cause, whether it be the bronchitic dyspnea itself, the nervous constitution of the patient, or an accidental excitation, the expiratory dyspnea due to the stenosing bronchitis becomes manifest or more pronounced simply because the quicker and deeper the breathing, the more potent become the previously mentioned mechanical causes of expiratory dyspnea. (See the section upon Dyspnea in Bronchitis.) With increased inspiration the lungs become more distended and the expiratory compression of the stenosed bronchi increases the expiratory dyspnea, especially when the expiration is of an active character. Any one may convince himself of the truth of this assertion by asking an asthmatic patient to breathe deeply at a time when there is little or no dyspnea present. The breathing will at once exhibit marked expiratory stridor and there is a demonstrable increase in the area of pulmonary resonance which differs in no particular from that observed in an asthmatic attack. In this experiment it is evident that neither spasm of the bronchial muscles nor an acute increase of secretion can be held responsible for the attack. The author's theory is also favored by the fact that the attack of bronchial asthma and the asthmatic disposition in general may be largely influenced by regulation of the respiratory excursion as well as by remedies which diminish the irritability of the respiratory center.

In bronchial asthma, therefore, there is a tendency to retardation of the breathing and particularly to a prolongation of the expiration. Inspiration and expiration are usually associated with stridor, but this stridor is more marked during expiration than inspiration. The absolute number of respirations may be diminished; or an increase in rate which would correspond to the amount of subjective dyspnea may be prevented. This depends upon the degree and the extent of the bronchial stenosis. In bronchial asthma, as in stenosing bronchitis, we may, therefore, observe either a diminished, normal, or increased frequency of respiration. The conditions are analogous to those in emphysema. (See next section.)

7. Dyspnea in Emphysema.—Pulmonary emphysema causes dyspnea because the lung is in a permanent condition approximating the inspiratory position, and because with inspiration and expiration it makes but small excursions from this position. Besides this, pronounced emphysema destroys numerous alveolar septa and their capillaries, thus diminishing the breathing surface very extensively. For this reason the dyspnea of pure uncomplicated emphysema is evidenced by rapid and superficial respiration. When the patient is quiet, the disturbance remains slight, but when some physical exertion makes extra demands upon the respiration, the dyspnea increases very decidedly. As a rule, patients with emphysema appear for the treatment of marked dyspnea only when this affection is complicated by a bronchitis (usually the dry variety). Consequently, in emphysema the same influences which we have just discussed in bronchitis tend to render the respiration now quicker and now slower. The tendency to retardation is very pronounced, because the bronchitis complicating the emphysema is usually

diffuse and produces a stenosis of most of the bronchi. The loss of elasticity in the emphysematous lung especially promotes a retardation of breathing and prolongation of expiration. But the dyspnea in emphysematous bronchitis is not always associated with a slowing of respiration, for the system will accommodate itself to the respiratory obstruction, with or without an increase of respiration, depending entirely upon the proportion between the extent of loss of elasticity in the lung, the degree of bronchial stenosis, and the amount of respiratory power. As a matter of fact, in the bronchitis of emphysema there is very often a certain amount of increase in the frequency of breathing. Still the subjective oppression outweighs the slight increase so decidedly that, unless we count, the impression is made that the respirations are slow, although actually they may be 20 to 25 a minute. In some cases this tendency to retardation leads to an actual diminution in the number of respirations; in other cases, only to a lack of any increase; in still another class of cases, to an increase in respirations which is but slight in proportion to the subjective dyspnea. Thus, the bronchial dyspnea of the emphysematous may be characterized as a dyspnea with a prolonged expiration and expiratory stridor (so-called expiratory dyspnea), and also with a more or less pronounced tendency to a diminution in the frequency of the breathing. These conditions are unchanged if, as is often the case, the emphysema is complicated with bronchial asthma.

8. So-called Uremic Dyspnea of Nephritis.—This exhibits no uniform symptom-complex. Only those cases should be designated as uremic asthma in which the breathing is characterized by prolonged expiration. In such cases we are led to suppose that a true bronchial asthma is present and that it is due to a uremic bronchitis associated with a uremic change in irritability of the respiratory center. (See p. 96 et seq.) Many dyspneic conditions in nephritis are, however, erroneously considered uremic. They depend rather more upon some cardiac disorder, upon the accompanying bronchial catarrh, or upon a beginning pulmonary edema, etc. Corresponding to the diversity in causation, these types of dyspnea vary decidedly in their character. It should be mentioned that dyspnea in nephritics is particularly frequent in combination with Cheyne-Stokes breathing. (See p. 88 et seq.) In reference to exaggerated breathing in uremia see Fig. 42, p. 100.

9. Febrile Dyspnea.—A febrile elevation of the body temperature is nearly always combined with an increase in respiratory frequency. Even the artificial application of heat to the body will increase the respiratory rate, so that it seems plausible that the irritation of warmer blood upon the respiratory center is responsible for the febrile rise of the respiratory rate.

However, the frequency of respiration in febrile diseases with exactly the same degree of temperature may differ widely, so that the nature of the toxin probably exerts some direct influence upon the respiratory center. The increased respiratory frequency in fever probably corresponds to an increased demand upon the metabolism. Therefore, according to our definition (p. 90), we are correct in speaking of febrile dyspnea as well as of febrile polypnea.

The respiratory frequency found with a certain degree of fever varies with each individual case. Experience shows that unless some respiratory complication exists, only the severe types of fever increase the respiratory frequency very noticeably. Fig. 30, the curve of an uncom-

plicated typhoid, illustrates the usual ratio between temperature and rate of respiration.

10. Anemic Dyspnea.—Exaggerated Breathing in Diabetic Coma.—Dyspnea occurs in anemia (oligochromemia) because the available amount of hemoglobin is so small that only the most complete aëration will be sufficient to supply the demand for oxygen. With no mechanical impediment to respiration, the organism can adapt itself very completely to the altered conditions. This is accomplished by a simultaneous increase in the frequency and in the depth of respiration. The resulting dyspnea produces a peculiar clinical picture, for the respirations are not only rapid, but also of maximum depth. This type is observed especially in pernicious anemia; rarely, however, in other disorders.

The same type of breathing is observed in diabetic coma,¹ and this phenomenon has been described by Kussmaul as “exaggerated breathing” (*grosse Atmung*). It is probably dependent upon the acidosis, as a result of which the alkalinity of the blood is diminished, the tissues are not sufficiently freed from carbon dioxide, and the respiratory center becomes abnormally irritable.

11. “Mixed” Dyspnea—Inspiratory and Expiratory.—Thus far we have been discussing the various factors which determine the different types of objective dyspnea. Two main types occur: (1) breathing with increased frequency and (2) slowed breathing with increased depth. In the former “mixed dyspnea” inspiration and expiration seem equally accelerated. In the latter, inspiration and expiration are affected differently; in some cases the inspiration, in others the expiration, appearing prolonged. One type is termed “inspiratory dyspnea,” the other “expiratory”; because in the one it is principally inspiration, and in the other expiration, which is rendered more difficult. In this connection compare the paragraphs on the types of dyspnea in obstruction of the upper air-passages in bronchitis, in emphysema, and in asthma.

Inspiratory dyspnea can usually be distinguished immediately by inspiratory, *expiratory dyspnea* by expiratory, stridor, without necessarily estimating the length of the two phases of respiration. If the examiner be inclined to do this, he should remember that normally expiration lasts longer than inspiration.

12. Observations upon the Teleology of the Forms of Dyspnea.—The individual forms of dyspnea have been explained in the preceding sections as though the organism in each instance voluntarily selected that modification of respiration which was best adapted to the existing condition. Such an explanation might be objected to upon the ground that dyspnea has nothing to do with a modification of a voluntary movement and consequently that the demonstration of the utility of the modification does not furnish a sufficient explanation for the particular respiratory mechanism. In answer to this we would call attention to the fact that the demonstration of utility alone can by no means constitute an explanation, but that the explanation of the occurrence of the particularly appropriate phenomenon is given by the fact that the best adapted means offers the greatest chance of phylogenetic maintenance. Experience teaches us that this is true not only for voluntary action, but also for automatic movement, the utility of which may be demonstrated in almost any portion of the body. Pathologic automatisms also not infrequently arise through the medium of voluntary actions.

GRAPHIC RECORDS OF THE FORMS OF BREATHING IN DISEASE (PNEUMOGRAPHY)

The graphic investigation of the respiratory movements in disease which was formerly neglected as compared with similar studies of the pulse has been recently elaborated, particularly by Hofbauer, and has furnished interesting results.

Fig. 39.—Respiratory curve of normal subject: *J*, Inspiration; *E*, expiration (reduced from Hofbauer).

A great variety of appliances may be employed to record the respiratory movements. In the Bern clinic we usually simply strap a cardiographic instrument, such as that of Jaquet's cardiosphygmograph (see Cardiogram), about the chest in such a manner that the "pelotte" of the air-chamber rests upon an area distant from the cardiac region instead of upon the apex-beat. The movements of the particular portion of the thoracic wall are transmitted by the air-chamber to the recording

Fig. 40.—Respiratory curve in the exaggerated breathing of diabetic coma: *J*, Inspiration; *E*, expiration (reduced from Hofbauer).

appliance of the original or simplified Jaquet's cardiosphygmograph (see p. 126 et seq.) and traced upon a smoked strip of paper. Mackenzie has shown that a small funnel may be employed as a pneumatic appliance for recording the breathing graphically, just as is the case with the recording of the venous pulse. (See pp. 127 and 128.) The small funnel is held upon the jugulum or the supraclavicular fossa. By any of these simple procedures respiratory curves may be obtained which are

Fig. 41.—Respiratory curve in a case of recent pneumothorax: *J*, Inspiration; *E*, expiration (reduced from Hofbauer).

quite useful. If simultaneous records of other movements are not desired, the respiratory movement may be recorded without a special mechanism and without the employment of air-chambers with the ordinary Jaquet's sphygmograph or a similar appliance, if it be fastened about the chest in such a manner that the thoracic movements are transmitted to the pelotte. Respiratory curves obtained in this manner, like sphygmograms, may be differentiated by their height, by their steep-

Fig. 42.—Respiratory curve in the exaggerated breathing of uremia: *J*, Inspiration; *E*, expiration (reduced from Hofbauer).

ness, and by the direction of their ascending and descending limbs. The graphic record of the height of the curve, however, has even a more limited value in a respiratory tracing than in a sphygmogram, because, with the same apparatus, it is dependent upon the area selected. Since the height of the curve influences the steepness of the limbs, we can base no inference upon the absolute steepness of the limbs of the curve (the size of the tangential angle). In the analysis of a pneumogram the only points from which conclusions may be drawn are: the comparison of the steep-

ness of the ascending and descending limbs of the curve, the duration of the ascending and descending limbs, and the form of the ascending and descending limbs in relation to their convexity or concavity and in reference to the change of direction of the curve (maximum, minimum, and changing points).

A critical employment of the curves demonstrates that pneumography is a useful addition to our methods of clinical investigation, and some of the typical curves obtained by Hofbauer have consequently been reproduced here.

Particular attention should be called to the prolonged expiration in the respiratory curve of pneumothorax depicted in Fig. 41. This is not so apparent in the course of an ordinary clinical investigation, since there is no expiratory stridor, no actual bronchial stenosis being present as in bronchial asthma or stenosing bronchitis, for example. It may be immediately recognized, however, if the duration of inspiration and expiration be timed with a watch provided with a second-hand. The prolonged expiration in pneumothorax, indicating, as it does, increased resistance to expiration, certainly proves the existence of a closed or valve pneumothorax. It is also of particular interest because it shows the compressing effect of expiration upon the finer bronchi, assumed in the author's explanation of the forms of expiratory dyspnea (see p. 96 et seq.), because in pneumothorax this is evidently the sole obstacle to expiration. It is apparent also that anomalies of respiratory rhythm, such as Cheyne-Stokes and meningitic breathing, furnish fruitful subjects for pneumographic records. Quite a number of interesting respiratory curves are given in L. Hofbauer's monograph.¹

AUXILIARY OR ACCESSORY BREATHING; FORCED ATTITUDES IN DYSPNEA

In all types of dyspnea the economy ordinarily employs all the available aid to lighten the burden of the respiration. In this way a number of muscles are used for breathing which, under normal conditions, serve other purposes. These are the so-called accessory respiratory muscles, chiefly the scaleni, trapezius, levator anguli scapulæ, sternocleidomastoid, sternothyroid, thyrohyoid, serrati, and the pectorals. The last five mentioned muscles may serve as inspiratory muscles, their usual fixed attachment to the chest being made the mobile point, the other end becoming stationary.

We have already considered upon p. 23 how the erect posture facilitates the task of these accessory muscles (orthopnea), and the importance of constrained lateral positions with a unilateral obstruction to breathing. The abdominal muscles are the only ones employed as accessory muscles to expiration. Naturally they are chiefly active in expiratory dyspnea, but they may also be utilized to advantage in mixed and in inspiratory dyspnea to accelerate expiration and thus to facilitate a new inspiration.

If the dyspnea be very pronounced, various other accessory muscles to respiration may be called into play. Their activity is of certain diagnostic importance, although it must be acknowledged that they do not materially assist the respiration. The facial muscles of expression are examples. During inspiration they distend the openings of the mouth, and especially of the nose, to a maximum. The patient thus presents quite a characteristic and pitiful appearance. This dilatation of the alæ nasi is especially pronounced in small children with pneumonia. Such a maximal distention of the entrances to the respiratory tract may sometimes be of real value; but it ordinarily means that some effect of the vigorous respiratory stimulation has been transferred to related muscle groups.

RELATION OF OBJECTIVE DYSPNEA TO CYANOSIS AND TO SUBJECTIVE DYSPNEA; HABITUATION TO RESPIRATORY OBSTRUCTION AND TO DYSPNEA

Objective dyspnea serves to diminish both cyanosis and the subjective sense of dyspnea. This task is not always performed equally well. The more completely the dyspnea aërates the blood, the less danger to the individual; but cyanosis can only be entirely overcome when the obstruction to inspiration is slight. Wherever a marked obstruction occurs, some little—oftentimes considerable—cyanosis must persist. The economy then performs its functions with blood rich in carbonic acid and poor in oxygen, and the dyspnea only succeeds in preventing a progressive deterioration of the blood. In cases of chronic dyspnea the economy may become more or less accustomed to the cyanosis. This is evidenced not only by the relatively good maintenance of the other body functions, but also because the sense of subjective dyspnea, "air hunger," gradually and progressively disappears. Conversely, with the same degree of respiratory obstruction, the more quickly the latter develops, the more intense the subjective dyspnea.

Pneumothorax furnishes one of the most striking examples of the economy's power of adaptation to respiratory obstruction. After the sudden onset of the respiratory obstruction, both the objective and subjective dyspnea are at first very pronounced, but soon diminish. In pneumothorax this does not merely depend upon a simple adjustment of the economy to cyanotic blood any more than in other conditions. For in this type, as in many others, the disturbance itself is lessened by a number of complicated, compensatory factors which proceed especially from the circulatory system. This also becomes plain from the diminution of objective dyspnea. Among these compensatory factors is the increased production of red blood-corpuscles produced by dyspneic irritation of the bone-marrow, which, by increasing the hemoglobin supply of the body, enables the organism to meet its demands for oxygen even with an incompletely aërated cyanotic blood.

We need scarcely add that dyspnea with a slight degree of cyanosis suggests a far better prognosis than dyspnea with pronounced cyanosis.

SPIROMETRY AND PNEUMATOMETRY

Spirometry and pneumatometry, *i. e.*, the mensuration of the vital capacity and of the respiratory pressure variations in the upper air-passages, have not as yet acquired any great diagnostic importance. This failure is due to the great difficulties in technic and to the pronounced influence of practice in those examined. Readers who wish to study thoroughly this method of examination should consult textbooks upon physiology and several of the original works upon pneumatometry.¹

The pneumoscope described by Bloch² seems to be the most useful for clinical purposes. Without determining the respiratory pressure manometrically, this instrument calculates the respiratory power by estimating the minimum diameter of a breathing cannula held in the mouth through which a sufficient quantity of air may be breathed. More accurate information of the respiratory mechanism can usually be obtained by pneumography (see p. 100 et seq.) and by directly measuring the thoracic excursions with a tape-measure than by spirometry or pneumatometry. (See p. 29 et seq.) Winternitz,³ however, has recently advocated the employment of spirometry in pleuritic exudates to estimate the quality of the respiration.

CHARACTER OF THE VOICE UNDER PATHOLOGIC CONDITIONS

Pathologic alterations in the voice arise partly from demonstrable disorders of the vocal organ proper (the larynx) and partly from other influences, either direct affections of, or disorders indirectly connected with, the respiratory apparatus. We shall mention here only such alterations of the voice as are of some diagnostic importance.

If the expiratory current of air does not make the vocal cords vibrate normally, the voice will be "*hoarse*," *e. g.*, in all inflammations, ulcerations, tumors, or paralyses of the cords. A hoarse voice always indicates some affection of the larynx and necessitates a laryngoscopic examination. If combined with inspiratory dyspnea, hoarseness is very suggestive of laryngeal obstruction. It may, however, be due to some general condition, *e. g.*, the loss of the cords' normal tone in weak, cachectic patients. Again, it may result from a fit of violent coughing. Here a paresis of the tensors of the cords is caused by the marked stretching of the cords during the glottic closure which precedes the cough. The hoarseness in phthisis, therefore, does not always mean an ulceration or even a catarrh of the larynx or cords.

In hysterical aphonia the voice is frequently lost without preliminary hoarseness; whereas a similar loss of voice is always preceded or introduced by hoarseness if the aphonia be due to anatomic changes in the larynx. This is a point of some diagnostic importance.

The voice may acquire a nasal twang as a result of alterations in the conditions of resonance in the mouth or nose. We distinguish a closed nasal voice from an open nasal voice. The former is observed when the nasopharynx or the nasal cavity itself is obstructed by any pathologic products, such as tumefactions of the mucous membrane, polypi, adenoids. The latter, the "open nasal voice," is observed when anything prevents the normal closure between the nasal cavity and the mouth, *e. g.*, palate paralysis, cleft palate, syphilitic affections of the palate, etc.

Aphonia (lack of voice) results either from an inability to approximate the vocal cords or from a prevention of the normal vibration. It may be preceded by hoarseness.

The voice is, moreover, very dependent upon the general condition and upon the thoracic organs. Patients who are very ill usually have a weak voice, corresponding to their general muscular weakness. In diseases of the respiratory and circulatory organs the voice is affected by the disturbed respiratory excursions and by the various sorts of dyspnea. In many patients with heart disease the voice (*i. e.*, the cord tonus) is a very delicate indicator of the condition of their general circulation—it becomes weak and feeble when they fail, and full and sonorous when they improve. In painful affections of the lungs or pleura and in peritonitis the voice becomes characteristically feeble, soft, and often broken. Cholera patients speak with a "toneless" voice (*vox cholERICA*), and the moribund with a faint, scarcely audible voice. Further reference will be made to these and similar points in the section on Auscultation (bronchophony).

COUGH

A cough consists of a single or of a consecutive series of explosive expiratory movements produced by abdominal pressure, which result in overcoming the preliminary closure of the glottis. It is a very important *reflex act*, serving the purpose, on the one hand, of expelling any foreign bodies which may have become lodged in the respiratory passages, and, on the other hand, of expectorating any material which may have accumulated there from some pathologic process, *e. g.*, bronchial or alveolar secretions, effused blood, pus which has perforated into the bronchi, disintegrated necrotic or tuberculous lung material, etc. A cough may be excited from various places in the body. The commonest type of cough is one in which the reflex arises from the region supplied by the sensory branches of the vagus. Experimental investigations have shown (especially Nothnagel's) that irritation of the laryngeal mucous membrane *above* the vocal cords produces spasmodic closure of the larynx, but no cough. Coughing will, however, be induced if the irritation affect the parts *below* the vocal cords. Under pathologic conditions, however, there is no doubt that affections of the pharynx and nasopharynx may produce cough. The most sensitive areas, as shown in Nothnagel's experiments, are the interarytenoid mucous membrane and the region of the bifurcation of the trachea. Coughing may also be excited from any other part of the tracheal, as well as from all parts of the bronchial, mucous membrane, but not from the pulmonary parenchyma proper.

Experimental results do not agree as to whether a cough can be excited directly from the pleura; but it seems probable, judging from experience with individuals whose pleura has been opened. From a teleologic standpoint such experience is of no value, since the results obtained may be explained by a pathologic radiation of the excitation. Upon the whole, the susceptibility to cough-exciting influences seems to diminish as we pass from the larynx toward the finer bronchi, because, from apparent reasons (the diminished expulsive power of coughing, the greater effectiveness of the ciliary movements), coughing is of less teleologic importance for the deeper respiratory passages than for the upper ones. This is in accord with the fact that unusually violent paroxysms of coughing indicate, with a fair degree of probability, the larynx and the trachea as the site of origin.

These are the most important sources of the excitation of coughing, but there are other less common ones. In some individuals coughing may be produced by irritation of the pharynx or of the base of the tongue, or occasionally of the esophagus. Coughing has been observed very exceptionally to result from tickling the external auditory canal (auricular branch of the vagus) or from manual pressure upon the spleen or liver. Some people cough as soon as their feet become cold or whenever their body surface is exposed. This suggests the therapeutic value of warm clothing in diseases complicated with a cough. This phenomenon, which possesses no teleologic explanation, probably comes under the head of the pathologic radiation of irritations from one nerve area to another. The existence of a stomach cough is very doubtful, although the lay public speak of it very frequently. Cough has not as yet, however, been experimentally excited from the stomach, and the so-called stomach

cough, which is so common in drunkards, can probably be most satisfactorily explained by assuming that an affection of the pulmonary passages [or pharynx.—Ed.] is combined with the stomach disorder.

Nervous Cough.—The so-called nervous cough merits a few words. We cannot deny the possibility of a nervous cough if we consider that a cough can be produced by an abnormal excitability anywhere in the course of the coughing reflex arc. When such reflex excitability is accentuated sufficiently, even physiologic irritants may cause a cough. As a matter of fact, a purely nervous cough is a very rare occurrence, and should only be diagnosed as such when it is observed in an exquisitely nervous or hysteric person, and when at the same time it differs decidedly from the ordinary type of cough. Under no circumstances is such a diagnosis justifiable from exclusion, *i. e.*, because the cough is the only sign of disease of the respiratory tract that can be made out from physical examination. It is well known that a cough frequently precedes all other signs of tuberculosis by weeks, often by months. (See under Barking Cough.)

Much more frequent than a purely nervous cough is one which is disproportionate to its cause (*i. e.*, secretion or inflammatory irritation of the air-passages), on account of an abnormal excitability of the coughing reflex. In such cases soothing remedies afford great relief.

On account of the rarity of other causes, a cough is usually an important symptom for the recognition of some state of pathologic irritation in the region of the respiratory branches of the sensory vagus. This irritation is in many cases produced by the accumulation of secretion in the air-passages. Experience teaches us that a cough caused by accumulation of secretion differs from the other types of cough. This difference is often appreciated by the laity. Its task, which is generally fulfilled, is to remove the secretion. It thus acquires a peculiar ring, recognized as a combination of the noise of the cough explosion with the noise of the moving secretion. (See later Râles, Rattling.)

Such a cough is called a **moist** or **loose cough** as contrasted with a **dry cough**, in which either the secretion is too tenacious to be set in motion or no secretion exists. The acoustic distinction between a moist and a dry cough is of considerable diagnostic importance, because the secretion is by no means always expelled from the mouth by the cough and so appreciated by the patient and the examiner, but very frequently after leaving the larynx is unconsciously swallowed.

There are certain other important peculiarities in a cough which may point to the cause of the disease.

The **peculiar rough barking cough** observed in simple and croupous laryngitis is characteristic of swelling without marked ulceration of the vocal cords. Here the voice may be clear, but it is usually very hoarse or aphonic. The barking tone is probably due to the swelling of the false cords which aid in closing the glottis. A similar barking is sometimes observed in the cough of hysteric individuals. Here the laryngoscopic examination proves that it is due to some abnormal innervation without any swelling. With a certain amount of practice one can really cough with a bark by adding phonation to the cough impulse. Like most other hysteric phenomena, it can be reproduced voluntarily. If not associated with swelling of the larynx, a barking cough suggests its hysteric nature.

If the margin of the vocal cords be irregular from deposition of

secretion or from ulceration, the cough is equally rough but not barking, and the voice is hoarse. If the closure of the glottis be imperfect on account of marked ulceration of the cords or on account of paralysis of the approximating muscles, or, if there be paresis of the expiratory muscles or general debility, the cough is noiseless. This peculiarity is observed in phthisis of the larynx, in paralysis (bulbar paralysis, myelitis), in any patient who is weak or severely ill. If a patient be unable to approximate the glottis perfectly, he may instead be compelled to close the mouth for the purpose of coughing, and then the resonation from the distended buccal cavity will furnish a very hollow ring to the cough. Such a hollow ringing is so generally observed in advanced phthisis that even the laity appreciate its prognostic significance.

A **hacking cough** consists of a series of very weak, frequently repeated coughing explosions. It is to be attributed to the mildness of the irritant, which in these cases is usually continuous and is not dependent upon any great amount of secretion. A hacking cough is most commonly observed in chronic catarrh of the upper air-passages, in pharyngitis and laryngitis, and especially in beginning pulmonary tuberculosis; hence its importance.

Conversely, **violent coughing paroxysms** are observed in acute, intensely irritated conditions of the air-passages from acute inflammations or from foreign bodies in the air-passages; in "swallowing the wrong way"; in affections of the air-passages associated with a profuse secretion, especially where cavities or bronchiectatic dilatations empty themselves periodically (see p. 24), and finally in *whooping-cough*. In the last-mentioned affection we may attribute the cause to the abundant production of glairy mucus and to the increased irritability of the nervous coughing mechanism. The "*whoop*," so important for diagnosing this disease, is a resounding crowing or whistling inspiration, combined with a spasm of the glottis, and separates individual groups of coughing attacks. The glottic spasm is evidently due to some radiation of the irritation from the coughing center to the neighboring structures of the central organ, and depends merely upon the intensity of the irritation. During violent coughing paroxysms of other diseases we sometimes observe resonant inspirations very much like this whoop, but so rarely that the "crowing inspiration" is the most important diagnostic sign of whooping-cough.

Vomiting sometimes complicates very intense coughing paroxysms; it is due to the central diffusion of the irritation.

Hemorrhage into the skin or mucous membranes, unconsciousness, or even epileptoid convulsions may be produced by the general venous congestion due to compression of the intrathoracic veins.

A physician must be very careful in taking the history of a patient in regard to coughing. So long as the cough or the hacking causes neither inconvenience nor discomfort, patients, especially the phthisical, persistently deny that they cough, even when the physician hears the hack himself. By imitating the sound and movements of such a "hack," a physician can sometimes get the patient to acknowledge that he does "hack," but that he never considered it a cough.

It must, however, be acknowledged that some cases of phthisis or bronchitis with very intense inflammation of the lungs occur without any cough or even a "hack." Here the secretion is probably brought up to the vocal cords by the motion of the cilia of the mucous membrane, and is then removed by "clearing the throat." If, as frequently happens, the secretion be swallowed, the patients neither cough nor expectorate.

LOCALIZED PROMINENCE OF THE CHEST IN COUGHING

As a result of the marked positive pressure and variations in the chest interior which are combined with the act of coughing, certain pliable portions of the thorax may be pushed forward at the commencement of the coughing spell in quite a remarkable way. If the glottis be closed, expiratory pressure distends the upper part of the chest chiefly, because the expiratory power fixes the lower thoracic aperture. In coughing, therefore, we generally observe a bulging forward of the upper intercostal spaces and apices of the lungs. Such bulging is especially prominent in emphysema, because the pulmonary resistance is impaired. The portion of the lung situated above the level of the clavicles shows an increase in volume, so that during a cough in emphysema we frequently notice that large swellings are produced above the clavicles. This phenomenon should not be confounded with the distention of the jugular veins during a cough, which is also oftentimes quite pronounced (p. 192 et seq.). If the lung tissue be infiltrated and shrunken, coughing will evidently not produce such an inflation. Hence a careful inspection of the supraclavicular fossæ sometimes furnishes important conclusions as to the condition of the apices in beginning tuberculosis.

PALPATION, SPHYGMOGRAPHY, AND SPHYGMOMANOMETRY OF THE ARTERIAL PULSE

Examination of the arterial pulse is of great diagnostic importance because it informs us of many things, such as the cardiac innervation, the force of the heart, the blood-pressure, and the condition of the peripheral arteries, and sometimes suggests the existence of valvular diseases of the heart or of fever. Many individual peculiarities must be considered and various methods employed to recognize them.

The commonest method and the one employed almost exclusively by practitioners is manual palpation of the arterial pulse.

Sphygmography, sphygmomanometry (tonometry), and sphygmobolometry are less used. Inspection and auscultation of the arterial pulse are much less important.

PALPATION OF THE PULSE

Any superficially placed artery may be utilized for the purpose of palpation; but we nearly always choose the same vessel, so as to have a certain uniform standard, experience, and practice in judging of the pulse. On account of its accessibility, the radial artery is usually selected. It is palpated between the styloid process of the radius, or the tendon of the supinator longus and the tendon of the flexor carpi radialis. An anomalous position of the artery or of the tendons will, of course, necessitate our trying another place. In doubtful or difficult cases the two radials should be compared, so as not to attribute erroneously some abnormality really due to local causes, to an alteration in the entire circulation. One radial not infrequently seems smaller than the other, whereas in reality it is merely a small branch which lies in the

ordinary place of the radial, the main trunk taking some abnormal course. Sphygmographic records have been employed to analyze carefully the differences in the pulses of the peripheral arteries, dependent upon their situation above or below an aortic aneurysm and upon whether or not the origin of the artery is narrowed (particularly common in aneurysms, Ziemssen). (See p. 152 et seq.) Such differences can also be appreciated by comparative palpation of the accessible arteries.

In palpating the pulse the index-finger is usually pressed upon the artery with a varying amount of force. When a certain amount of pressure is exerted, the artery is found to expand and to lift the fingers with every heart-beat, and it is this lifting which is known as the pulse. It must be noted that under normal conditions a certain pressure of the palpating finger is necessary for a distinct perception of the pulse, because Marey has shown (*La circulation du sang*, 1881) that the increase in caliber of the arteries with the pulsation is so slight that the pulse of a vessel as large as the abdominal aorta is scarcely perceptible if the outer surface of the artery be simply touched instead of pressed upon. We may consequently state that if the pulse be palpable without pressure, the pulsations will usually be visible (jumping arteries), and the condition present is one of abnormal volume or celerity of the fluctuations in [blood] pressure.

Palpation with one or two fingers is sufficient to determine the frequency and the rhythm; but we need three fingers for judging the form and celerity of the pulse-wave and the height of the blood-pressure.

CHARACTER OF THE ARTERIAL WALL

Palpation of the arterial wall permits us to determine whether arteriosclerosis is present or not, and whether the pulse-wave is modified by any factors in the wall itself.

The most important thing to determine is the amount of elasticity or rigidity and the thickness of the wall of the arterial tube. This can be most effectually determined by rolling the artery back and forth under the finger and by running the finger along its length, at the same time being careful to prevent the influence of the blood-current by compressing the vessel with another of the fingers. The artery is *soft, thin-walled, and elastic* in young and healthy individuals; but in *arteriosclerosis* or where the blood-pressure is permanently raised by an increase of the vasomotor tonus (chronic nephritis, lead-poisoning, plethora) we can often distinctly appreciate the *increased resistance* and thickening of the walls. The tortuous character of the artery so frequent in these conditions is caused by a definite elongation. At the same time some arteries may be tortuous without any arteriosclerosis, *e. g.*, the temporal arteries. The deposit of lime in the wall, which is observed in very pronounced cases of arteriosclerosis, can be felt very distinctly as rough, hard irregularities. Arteriosclerotic rigidity with even less marked changes, however, may usually be distinctly differentiated by its irregularity from the uniform hypertrophy of the arterial wall in chronic nephritis and other conditions of permanently increased blood-pressure. Although palpation is diagnostically important in determining the existence of arteriosclerosis of the peripheral arteries, it does not necessarily show whether the aorta, coronary arteries,

or other deep-seated vessels are normal or not. The arteriosclerotic changes may be very unevenly distributed, and the radial artery is one which shows no marked predilection for the changes incident to a generalized arteriosclerosis. Therefore, to demonstrate arteriosclerosis we should palpate as many as possible of the superficial arteries.

A persistently high-tension pulse is one of the most reliable indications of diffuse arteriosclerosis when the examination shows no other cause for it (nephritis, plethora, dyspnea); but even without high tension an extensive arteriosclerosis may exist; and the absence of high tension or rigid arteries is not sufficient evidence to exclude it definitely, especially in the case of the aorta and coronary arteries. On the other hand, proof of the existence of arteriosclerosis is essential although, unfortunately, many physicians erroneously diagnose this arterial change by a process of exclusion, merely because they are at loss to account otherwise for the existence of circulatory defects. Such a course is not justifiable even in case of elderly individuals, for all persons beyond a certain age do not necessarily exhibit arteriosclerosis; nor are arteriosclerosis and age actually identical conceptions. From an ethical standpoint, it is even more deplorable that any individual suffering with a circulatory disturbance not attributable to a valvular lesion should be alarmed by an immediate diagnosis of arteriosclerosis or arterial calcification.¹ The greater number of the maladies which are now hastily diagnosed as arteriosclerosis are nothing else than myocarditic or neurocarditic affections which it may be quite possible to arrest or cure. Bäumlér rendered a great service when he called attention to the faulty routine diagnosis of arteriosclerosis and also pointed out that it not infrequently happens that localized arteriosclerosis is present in the extremities most used (particularly in the arms), and that such changes are of but little importance to the general circulation.

CHARACTERS OF THE PULSE

FREQUENCY OF THE PULSE

The pulse frequency (*i. e.*, the number of beats in a minute) is estimated by counting the radial pulse. It is advisable to count an irregular pulse for at least one minute and then to repeat, for otherwise the count may not be accurate. If repeated counts furnish different figures, the extremes should be noted.

A great many influences affect the frequency of the pulse physiologically, so that it is advisable to estimate the rate under conditions which are as nearly alike as possible, or, in case this cannot be done, to make allowance for the action of these influences in forming an opinion. In sensitive people any mental excitement whatsoever decidedly influences the pulse-rate. The physician's entrance is enough to cause a marked rise in the pulse, so that at the bedside it is advisable to delay counting the pulse until after conversing with the patient for a while.

Any bodily exertion or movement increases the pulse-rate. After running, gymnastics, fencing, or mountain-climbing the rate may be very greatly increased and still be within physiologic limits. Even the quieter motions in bed, voiding urine, or evacuating the bowels, materially increases the pulse-rate in very sensitive or very ill patients. After moderate activity the increase in rate soon subsides, but after prolonged, fatiguing exertion it may persist for some time. The pulse-rate, furthermore, depends upon the position of the body. After lying down, sitting up increases the frequency; so does standing up after sitting. This rise may be only transitory, due to the muscular exertion attendant upon the change of position, or to some extent permanent so long as the position is maintained.

¹ The popular and unscientific expression "calcified arteries," which has alarmed many a layman possessing an encyclopedia, has no basis in fact, since calcium salts are very often absent in arteriosclerosis and usually play an entirely subordinate rôle.

Guy found that in fasting, healthy men who had previously rested the pulse-rate was 66 to the minute while prone, 71 while sitting, and 81 when standing.

Ingestion of food increases the pulse-rate for several hours during the period of digestion, the amount of increase varying according to the quantity of food. The daily variations of the pulse are only partly due to the influence of the meals; for daily variations approximately parallel to the daily variations of temperature are observed even in fasting individuals. They usually amount to only a few beats.

Generally speaking, a high blood-pressure produces a slowing of the pulse, a low blood-pressure an increase in its rate. There are, however, many exceptions to this rule, although it undoubtedly possesses some teleologic importance. Marey attributes the increased pulse-rate in standing up as contrasted with lying down to the difference in blood-pressure. This, he believes, is higher in the recumbent posture.

[Meylan's blood-pressure determinations in the vertical and horizontal postures in a large number of students at Columbia University, my own in a series of school boys¹ and in many healthy and diseased adults, have convinced me that Marey's explanation and his premise upon which it is based are both incorrect. In general, an athlete in good training shows a slow pulse in the recumbent posture, and its frequency increases but a few beats a minute upon standing. The systolic blood-pressure, however, is apt to be 5 to 15 mm. higher in the erect than in the recumbent posture. Meylan regards the reverse (recumbent pressure greater than erect pressure) as an indication of physical or circulatory weakness. So far as they have gone, many of my observations suggest the same conclusion.—ED.]

Respiration usually influences the pulse-rate; during inspiration it is increased, during expiration diminished.

Coughing or Valsalva's experiment produces a marked increase in the pulse-rate. In the latter the increased frequency persists longer than the increased intrathoracic pressure.

The time of life has a very distinct influence upon pulse frequency. Rollet² quotes the following figures, collected from various observers, as averages:

Age.	Pulse-beats to minute.	Age.	Pulse-beats to minute.
End of fetal life.....	144-133	10th to 15th year.....	91-76
Newborn and 1st year of life .	143-123	20th to 60th year.....	73-69

Vierordt³ gives the following detailed table for childhood:

Age.	Pulse-beats a minute.	Age.	Pulse-beats a minute.
1 year.....	134	7- 8 years.	94.9
1-2 years.....	110	8- 9 ".....	88.8
2-3 ".....	108	9-10 ".....	91.8
3-4 ".....	108	10-11 ".....	87.9
4-5 ".....	103	11-12 ".....	89.7
5-6 ".....	98.0	12-13 ".....	87.9
6-7 ".....	92.1	13-14 ".....	86.8

The pulse-rate generally diminishes with the advancing years until the age of sixty, after which time it begins to increase slightly. Sex also has some influence. According to Guy, women average 7 to 8 beats a minute more than men of the same age. In individuals of the

¹ Potter and Harrington, Jour. Amer. Med. Assoc., vol. liii, No. 24, p. 1957.

² Hermann: Handbuch der Physiologie, vol. iv, 1.

³ H. Vierordt: Daten und Tabellen, Jena, G. Fischer, 1888.

same age and sex the pulse-rate varies according to the height; it is slower in tall than in short persons.

Sometimes the pulse count at the wrist is less than over the heart. In such an event the latter must be the accurate measure of the heart's frequency, and we naturally conclude that the cardiac power has become affected, so that some of the pulse-waves are not transmitted to the peripheral arteries. Such an omission of individual beats makes the pulse sequence irregular, so that the examiner then turns to the heart. If the radial pulse be perfectly regular, we should not think of the existence of any difference between it and the heart-beat unless only some of the beats are strong enough to be transmitted to the radial artery, such as in pseudobradycardia (see p. 113), pulsus alternans and bigeminus, heart bigeminus, hemisystole, systolia alternans (see later sections upon the Modern Analysis of the Irregular Pulse and upon the Cardiac Impulse).

The pulse frequency, like the body temperature, can be conveniently represented upon a chart in the form of a curve. The variations of both can thus be very accurately compared at a glance.

Increase of Pulse Frequency; Tachycardia; Pseudotachycardia.—*Fever* is one of the most common causes of an accelerated pulse-rate (tachycardia). The temperature and the pulse-curve in fever usually run parallel. Liebermeister estimated that the pulse frequency was increased by about 8 beats for every degree of temperature. So long as pulse and febrile disturbance run parallel in this way, such a harmonious preservation of the functions may be regarded as relatively favorable. On the other hand, the more the acceleration of the pulse exceeds the elevation of temperature, the graver the prognosis, because too rapid a pulse-rate usually means some serious damage to the circulation, either to the heart or to the vasomotor system. If the patient be resting quietly, a pulse of 140 to 160 in fever is always of grave significance. Under various conditions of fever the pulse frequency and the temperature may follow an entirely different course. Such a divergence of the curves is of very great diagnostic importance. A high temperature with a slow pulse is observed chiefly in *febrile brain diseases*, in which the pressure upon the brain is responsible for the slowing of the pulse, as in *tuberculous meningitis* (Fig. 43); again, in a *combination* of a *febrile disease* with a *cardiac disturbance* which causes bradycardia (adiposity, sclerosis of the coronary arteries, myocarditis). The converse, a high pulse-rate with an abnormally low temperature, is characteristic of the symptom-complex of acute circulatory weakness included in the name *collapse* (Fig. 38).

There are numerous other exceptions to this rule of parallelism of the two curves, although most of them are less pronounced than the examples just cited, *e. g.*, in typhoid fever the pulse frequency is notoriously moderate as compared with the height of the temperature (Fig. 30). This peculiarity is often serviceable in differentiating typhoid fever from acute miliary tuberculosis or septicopyemia. For in the last two mentioned the pulse-rate is almost always accelerated out of proportion to the rise of temperature. Conversely, in pulmonary tuberculosis a very rapid pulse-rate is frequently observed with only a moderate rise of temperature or even with no rise at all. Yet the rectal is often unexpectedly higher than the mouth temperature. Children usually exhibit a relatively rapid pulse-rate with fever.

A rapid pulse-rate is, furthermore, found in affections of the heart or of the nerves. Valvular diseases in the stage of disturbed compensation, endocarditis, pericarditis, dislocation of the heart by processes in its vicinity which limit the space, exophthalmic goiter, nervous palpitation, nervous tachycardia—all of these diseases are or may be associated with a more or less considerable increase of the pulse-rate, to a certain extent proportional to the severity of the affection. Very imperfect explanation has been found for the cause of the increased pulse-rate in these cases. Mackenzie¹ has shown that the symptoms of the so-called paroxysmal tachycardia are probably due to an enormous accumulation of extrasystoles. The sphygmograms of markedly accelerated pulses corroborate his view in that normal pulse-periods

Fig. 43.—Relation of temperature and pulse frequency in tuberculous meningitis.

of varying length appear frequently, to which the accelerated pulse holds the relation of true extrasystoles. (See p. 154 et seq.) The undoubted occurrence of groups of extrasystoles in addition to the attacks of pronounced and long-continued tachycardia also favors this conception.

An increased pulse-rate also occurs combined with all sorts of pain. Under some conditions not yet understood the reverse at times occurs, *i. e.*, a slowing of the pulse. (See p. 113.) The reflex influence upon the cardiac nerves is the probable cause in both cases.

Atropin and alcohol are the two most important of the numerous poisons which accelerate the rate of the heart.

Not infrequently, under pathologic conditions, the acceleration of

¹ The Study of the Pulse, 1902, p. 124, et seq.

the pulse due in a healthy individual to physiologic influences (p. 109 et seq.) may reach an excessive degree so far as duration and intensity are concerned. This always points either to some damage to the heart itself or to its nervous mechanism. Thus, in chlorotics or in other weakly individuals even very slight exertion (stair climbing) will greatly increase the pulse-rate; and this increase is usually associated with the subjective sense of palpitation of the heart and of dyspnea. This phenomenon is of great diagnostic value from a functional standpoint. If diastolic be misinterpreted as a pulsus bigeminus or alternans, as might happen in Fig. 63, p. 142, we could speak of a pseudotachycardia.

Diminution of the Pulse-rate (Bradycardia; Pseudobradycardia).—A noticeably slow pulse (bradycardia) does occur, although rarely, as an individual, non-pathologic peculiarity in a healthy person. A very pronounced slowing of the rate, to as low as 20 or less beats to the minute, is observed pathologically in certain diseases of the heart muscle, especially in the *fatty infiltrated heart* and in *sclerosis of the coronary arteries*. A greater or lesser degree of retardation is sometimes observed in *compensated aortic stenosis*. *Cachectic individuals* usually exhibit not only a low temperature, but also a slow pulse-rate (carcinoma of esophagus, etc.). Similar results are observed in convalescence.

A temporary slowing of the pulse (to a little below normal) is often found in acute febrile diseases after the crisis. When, despite the critical drop of temperature, the pulse remains high, there is always reason to suspect a "pseudocrisis." (See Fig. 29.) In certain painful affections (*e. g.*, gall-stone colic, lead colic), unless fever be present, a slowing of the pulse is more frequently observed than an increase. Icterus often produces retardation, due to the toxic action of the biliary salts. This, however, usually disappears when the jaundice is prolonged, either because the heart becomes accustomed to the intoxication, because the production of the biliary salts is diminished, or because their elimination is more complete. The slowing of the pulse in acute cerebral pressure is of particular diagnostic importance (meningitis (Fig. 43), fracture of the skull). Unless acute exacerbations occur, chronic cerebral pressure usually does not cause any slowing of the pulse. *Shock* sometimes causes an excessive slowing of the pulse. Rapid emptying of peritoneal or pleural effusions sometimes diminishes the pulse-rate.¹ Some drugs (digitalis, etc.) produce a slowing of the pulse.

In arrhythmia, when only the larger pulse-waves are palpable in the peripheral arteries, it is natural to assume erroneously that the pulse is slowed. The error will be disclosed by auscultation of the heart and palpation of the apex-beat. It goes without saying that such a control is necessary with every irregular pulse. It is not so well known that even with a regular pulse every bradycardia should be similarly controlled. As a matter of fact, there is such a thing as rhythmic pseudobradycardia, in which there is a decidedly slowed pulse in the peripheral arteries, while palpation and auscultation of the heart disclose the double pulse frequency. The phenomenon usually depends upon the existence of bigeminus (see Fig. 60, p. 138, and Fig. 76 a, p. 151), in which the second pulse (extrasystole) is not sufficiently recorded in the peripheral pulse-wave to appear as an independent pulse (see Fig. 153, "apparent

¹[Capps and Lewis (Trans. Assoc. Amer. Phys., 1907, p. 635) have found that two types of reflexes result from thoracentesis in the presence of an inflamed pleura: (1) A cardio-inhibitory type, manifested by a slow intermittent pulse with a great difference between systolic and diastolic pressures; (2) a vasomotor type, manifested by a steady fall in blood-pressure without a marked difference in systolic and diastolic pressures, and by a pulse that grows steadily weaker until it cannot be felt.—Ed.]

bradycardia," in the section Recording the Cardiac Tones, p. 312.) With these pseudobradycardias may also be included the phenomena described at p. 159 et seq., in which the auricles (or the right auricle) beat more frequently than the ventricles, whether it result from a conductive disturbance or from a complete dissociation of auricle and ventricle (Stokes-Adams' disease; see also Cardiac Impulse: Double Beat of the Heart). Most excessive bradycardias in cardiac patients probably have some such special genesis which may frequently be determined by an analysis of the radial and venous pulse-curves. (See p. 157 et seq.)

PULSE RHYTHM

Under normal conditions the pulse is regular or rhythmic, *i. e.*, the individual pulse-waves follow each other at equal intervals of time. Only slight transitory deviations from such regularity come within physiologic limits, and then principally under conditions which modify the pulse frequency as well. More pronounced irregularities of the sequence of beats, or *arrhythmia*, are probably all pathologic, and indicate either some distinct lesion of the heart or some purely functional disturbance of its activity, such as occurs in all sorts of conditions, with or without cardiac weakness.

According to Mackenzie, over one-half of multiparæ exhibit during pregnancy disturbances of the pulse rhythm, which are temporary and without unfavorable prognostic significance. In some individuals tea, coffee, and tobacco immediately produce arrhythmia of the pulse. Mackenzie imputes a very grave prognostic significance to the appearance of an irregular pulse during a fever in patients who otherwise have normal pulses, and states that a fatal outcome occurred in all his cases of croupous pneumonia which had an irregular pulse before the crisis, even though the irregularity was only occasional. It is certainly true, particularly in pneumonia, that the appearance of irregularity in the pulse is of very grave import, but the author does not care to subscribe absolutely to such a pessimistic belief in reference to arrhythmia in fever (such arrhythmia in pneumonia also is due to extrasystoles), because he knows patients who immediately develop arrhythmia with innocent febrile disturbances. Upon the other hand, a habitually arrhythmic pulse very frequently tends to become regular during fever.

We may differentiate between an *absolutely irregular pulse* (*pulsus irregularis*), which is usually at the same time much increased in rate (*delirium cordis*), and a *partially irregular pulse*. In one type of the latter the irregularities are uneven, *i. e.*, the intervals between the beats are sometimes shortened and sometimes lengthened without any sign of regularity. In the other type of the *partially irregular pulse* the irregularities are periodic, *i. e.*, they follow each other at regular and definite intervals.

Irregularities of rhythm are nearly always associated with inequality of the individual pulse-wave, *i. e.*, a *pulsus irregularis* is at the same time a *pulsus inequalis*. It is therefore advisable to defer the consideration of the various types of irregular pulse until after we have studied and understood the difference in quality of the individual beat. (See Sphygmography.)

CHARACTERS OF THE INDIVIDUAL PULSE-BEAT

The proficiency which different observers attain in the determination of the quality of the individual beat by palpation varies decidedly with their practice and skill. He who is less adept may obtain more accurate

information by employing sphygmography, sphygmomanometry, and sphygmobolometry. In addition to the regularity, the qualities which every physician should recognize by palpation without any especial instrument are: the celerity, the tension, the size and strength, and dicrotism.

Celerity of the Pulse.—By celerity is meant the degree of rapidity of the rise and subsidence of the individual pulse-wave beneath the compressing finger or, if the pressure be graphically recorded in the sphygmogram, by the steepness of the rise and fall of the curve. To recognize the degree of celerity by palpation three fingers should be employed, placing them along the course of the artery.

A *pulsus celer* is one whose wave rises quickly and descends quickly; a *pulsus tardus*, one whose wave rises slowly and descends slowly. Upon the fingers a *pulsus celer* produces the impression of a quick, sharp rap. This peculiarity is appreciated most distinctly when the pulse-wave is at the same time of considerable volume. Therefore, what is often called a *pulsus celer* is generally a full pulse as well. The pulse of aortic insufficiency is the most striking as well as the commonest example of a *pulsus celer*. It very frequently can be appreciated even by the eye as a noteworthy pulsation of the artery in the neck, and the diagnosis of aortic insufficiency made correctly at a distance. The abruptness of the ascent and of the descent of the pulse-wave do not take an equal part in producing this “rapping” sensation. For although the abruptness of the rise may be recognized without any particular training, it requires considerable practice to recognize the abruptness of the drop. Von Frey claims that the abruptness of the descent of the pulse-wave can be estimated only by means of the sphygmograph and not by palpation. But the author believes that an expert physician can perfectly well differentiate between a pulse whose sharp, bounding quality is due only to an abrupt onset of the wave and a pulse with an abrupt descent as well as ascent. The terms “*pulsus celer*” and “*pulsus tardus*” are especially well adapted to the cases in which both limbs of the pulse-wave are either steep or blunt. Where either the ascent or the descent alone is abrupt or gradual, this peculiarity should be specified. Thus, a pulse may be *celer* in its ascent and *tardus* in its descent. These conditions are explained more fully by Sphygmography upon p. 143 (Figs. 65–69).

Pulse Tension.—Consideration of Blood-pressure.—We consider under the term “pulse tension” the qualities of the individual pulse-wave which show the amount of pressure in the arteries. The difficulty is, however, that the term blood-pressure may be understood in quite different ways. The term blood-pressure ordinarily signifies the average or mean blood-pressure which physiologists have almost exclusively studied with the usual manometers in experiments upon animals. But the maximum or systolic and the minimum or diastolic blood-pressure must also be considered. In a healthy man or animal the variations of blood-pressure from the average are but of moderate degree, and so we ordinarily speak of “blood-pressure” without further remark when we strictly mean average blood-pressure. We do not know, however, whether the systolic variations in pressure under pathologic conditions are so very slight. Sphygmographic and sphygmomanometric observations (see later) seem to show that they are considerable. Therefore, under pathologic conditions, the systolic

or maximum, the average or mean, and finally the diastolic or minimum, pressure should be considered separately. (See Absolute Sphygmogram, p. 174 et seq.) A more distinct and uniform conception of the terms expressing the pulse tension is, therefore, essential, and these terms should be clinically correlative to blood-pressure. Just as we distinguish between a maximum, middle, and minimum blood-pressure, so should we differentiate between a maximum or systolic, an average or mean, and a minimum or diastolic tension of the arteries. The ordinary definition that tension is the measure of the amount of finger pressure which is necessary to compress the artery is not accurate, and is, therefore, inadequate to teach us how to palpate pulses correctly. It is better to define the maximum tension of an artery as the amount of force which is necessary to prevent the transmission of the pulse-wave to the periphery,¹ the minimum tension as the power necessary to compress an artery during cardiac diastole, and the average or mean tension as a certain average amount of power which will suffice to close the artery between systole and diastole. A disregard of the various meanings of the term arterial tension thus explains the variations in the description of one and the same pulse, one observer calling the tension high, another calling it low.

As the manner of palpating an artery varies, so do conclusions as to the pressure conditions in the artery differ. Usually—although only partly justifiably—most importance is attached to the maximum or systolic tension of the artery. This is determined ("dynamic" procedure of taking the pulse) by palpating the artery with three adjoining fingers along the long axis of the vessel. The distal finger compresses the artery so that no recurrent pulse-wave can reach the vessel from the periphery. The proximal finger exerts a gradually increasing pressure upon the artery until the middle finger, which should rest quite gently upon the vessel, can no longer feel the wave. The power used is the measure of the (heart) systolic or maximum tension of the artery. This procedure is imitated by von Basch's method of sphygmography (p. 163 et seq.).

The physical accuracy of his method of determining the systolic pressure, *i. e.*, the correctness of identifying the amount of pressure employed with the systolic pressure, is questionable. The same doubt applies to this dynamic method of palpation, for the reason that, besides the systolic increase of pressure, the vital energy of the pulse-wave has an important influence upon the result obtained. This vital energy is closely dependent upon the size of the pulse-wave, and the size in turn by no means runs parallel with the blood-pressure. We have not only the systolic blood-pressure to overcome in the procedure, but, generally speaking, a much greater pressure, because the recoil of the pulse-wave at the compressed point of the artery acts very much as a water-ram.

It will, however, be shown in the chapter upon Sphygmomanometry that this theoretic objection plays no important rôle in the practical results obtained by dynamic palpation. The conditions are identical with those in von Basch's and Riva Rocci's method of sphygmomanometry, in which, as shown at p. 166, the vital energy or the size of the pulse-wave does not markedly influence the value of the systolic pressure found. A greater objection to the determination of systolic pressure by palpation appears to be the fact that the force necessary to compress an elastic tube filled with fluid is dependent, not only upon the pressure within, but also upon the caliber of the tube. From Pascal's law of the hydraulic press it follows that every unit of surface of the vascular wall is subjected to the same pressure, so that when an attempt is made to compress an elastic vessel, the size of the area com-

¹ See the following pages for the doubts about identifying this exercise of power with the systolic pressure.

pressed must also be regarded, as well as the manometric pressure. Consequently, with the same manometric pressure a large vessel is just as many times as difficult to compress as a small vessel, as the surface of the former is greater than that of the latter. In sphygmomanometry this objection is happily overcome by the employment of a pneumatic compressor; in dynamic palpation, however, the objection seems to be a practical one. Experience, nevertheless, teaches that with training this objection can be overcome sufficiently in a great majority of cases, even in palpation, to estimate, at least approximately, the systolic tension as high, medium, or low. According to the author's view, this rather unexpected applicability of palpation is due to the fact that the palpating volar surface of the terminal phalanx bears a certain physical resemblance to a fluid "pelotte," and that the bony phalanx does not compress the artery directly, but indirectly through the medium of the hydraulic cushion of the finger-pulp. The conditions present are, therefore, quite similar to those in von Basch's sphygmomanometer. This completeness of the sense of touch is a new example of the teleologic adaptation of the human body, not only to the palpation of the pulse, but to similar palpatory tasks which were practised by aboriginal man (the determination of the ripeness of berries, etc.).

A beginner may facilitate his task by palpating the vessel through an interposed pneumatic cushion, as, for example, the pelotte belonging to the author's sphygmomanometer. (See p. 165 et seq.) The tube is clamped, and instead of being connected with the manometer, the pelotte is moderately distended, and placed between the artery and the palpating finger. When employed in this manner, it constitutes the simplest form of a palpatory manometer.

The author's so-called "static" method of palpating the pulse is as follows: If the radial artery be palpated with one, two, or three fingers, we observe that with a very slight pressure the appreciable pulsatory excursions of the artery are usually very small, but that they increase as soon as the arterial wall is somewhat more strongly compressed. With increasing pressure a maximum excursion is observed, after which any further increase of digital pressure diminishes the size of the pulse. The amount of pressure necessary to obtain the maximum excursion corresponds to a certain mean between the minimal, *i. e.*, the diastolic, and the systolic pressure in the artery, as is shown by the results obtained by sphygmomanometry. (See p. 180 et seq.) The increased excursion of the artery with increasing external pressure is evidently due to the fact that in the uncompressed artery a part of the pulsatory increase in pressure is absorbed by the tense arterial wall; when this tension of the arterial wall is relieved by pressure from without, the pulse-wave will be transmitted to the palpating finger with a minimum amount of loss and further increased by reflexion, so that the excursion of the palpating finger is considerably increased by both factors. While in the former edition the author held the opinion that the pressure exerted by the finger at the moment of maximum excursion corresponded to the minimum pressure in the artery, the comparative examination of the pulse by means of sphygmomanometry (see p. 180 et seq.), and the manometric determination of minimum pressure (see p. 175 et seq.), teach that the maximum excursions correspond to a certain mean pressure, in which the reflux and the relief of tension of the arterial wall are combined to the best advantage. It might, therefore, be said that this static procedure for determining blood-pressure by palpation gives information in reference to a mean arterial pressure, but it should particularly be remembered that this mean pressure is by no means the exact arithmetic mean between the maximum and the minimum pressure. When the finger pressure is increased until the palpating finger attains the maximum excursion, any further compression will, of course, diminish the excursion, since the pulse-wave is no longer able to overcome the resistance of the compressing finger. In this method the ability of estimating the pressure employed also depends upon the previously mentioned hydraulic peculiarity of the digital pulp.

In considering these theoretic difficulties, we can readily appreciate the fact that an especial skill in appreciating the relations of pressure accrues to the careful clinician only after years of practice and a long experience in contrasting and remembering differences in pressure. On account of such manifold difficulties in judging arterial tension it is advisable to supplement palpation by sphygmomanometry (p. 163 et seq.).

Custom has come to employ the expression "hard" or "tense" pulse (*pulsus durus*) as synonymous with increased arterial tension,

and "soft" or "relaxed" pulse (*pulsus mollis*) with diminished tension. Of course, we must not confuse these with the same terms applied to qualities of the arterial wall (softness *versus* rigidity of the artery) (p. 108). Again, these terms may at one time be applied to the systolic, at another to the diastolic, pressure. In nephritis and arteriosclerosis the diastolic as well as the systolic pressure is ordinarily increased.

In the latter, however, the pressure may be normal, particularly when the splanchnic area is not involved in the arteriosclerotic process. This peculiarity should never be employed to favor the diagnosis of arteriosclerosis. (See p. 109.) In reference to the diagnostic utilization of blood-pressures obtained by palpation, the reader is referred to the chapter upon Sphygmomanometry. (See p. 163 et seq.)

THE ESTIMATION OF THE SIZE AND ENERGY OF THE PULSE (The Strength, Power, or Volume of the Pulse)

When we determine the maximum excursion of the pulse beneath the appropriate pressure of the palpating finger in the "static" method, as just described, we determine that factor which is designated in the sphygmogram as the size or height of the pulse. Although this value is derived from the difference between the maximum and minimum arterial pressures, and consequently is proportional to the height of the absolute sphygmogram (the difference of the heights of the points in Fig. 101, p. 177), it has, nevertheless, an indefinite significance in reference to the estimation of the amount of work done by the heart, since the lifting power of the pulse-wave is dependent not only upon these differences of pressure, but also upon the diameter of the artery (Pascal's Law, see p. 141). In other words, with the same difference between maximum and minimum pressure the palpating finger will be elevated more with a large artery than with a small one. In estimating the work done by the heart, the size of the pulse consequently affords even less accurate conclusions than does the absolute sphygmogram (see p. 177), because the calculation includes an additional unknown factor, namely, the diameter of the artery.

When we come to consider the strength of the pulse, however, we find quite a different state of affairs. This idea of pulse energy, which the older physicians considered second in importance only to the hardness or tension, has been recently neglected, evidently as the result of the introduction of the exact methods of measuring blood-pressure. The entire attention of the practitioner has been directed to the statics of the arteries, and some who believe that the determination of arterial pressure is all sufficient even regard the determination of the strength of the pulse as less exact and less scientific, since it comes to us from a period when the palpation of the pulse was most rudimentary. Such a conception, however, is entirely erroneous, and it is urgently necessary to introduce again this idea of pulse strength or pulse energy in our clinical teaching, because it has been sufficiently shown by the author's investigations in reference to the absolute sphygmogram that the height of the curve or of the pulse-pressure (the arterial maximum and minimum pressure) is of but little value in estimating the amount of work done by the heart. This is due simply to the fact that static conceptions can never be made the measure of a movement as long as the resistance to that movement is unknown. The term strength or energy of the pulse,

upon the other hand, is a dynamic conception, and it is clear that it can give us information up to a certain point as to work done by the heart. For the facts upon which this statement is based the reader is referred to the section upon Sphygmobolometry. (See p. 180 et seq.) As the work done by the heart may be measured by the sphygmobolometer, so can the energy of the pulse be estimated by the sensation transmitted to the palpating finger. It is not the blood-pressure nor the height nor size of the pulse-wave, but the actual energy of the pulse-stroke, which is determined. Our organism is much better adapted to such an estimation of mechanical energy than it is to the estimation of arterial pressure, because in the latter Pascal's law is always responsible for certain difficulties, and while these may be overcome to a certain extent by practice, the law plays no part whatever in the determination of pulse energy. Although the pulse-beat in a larger artery develops a greater amount of energy according to Pascal's law, this is simply an expression of the fact that in this case the pulse energy is greater as a result of the larger volume of blood set in motion. The fundamental difference between this method of examination and the determination of the height or size of the pulse-wave becomes clearest when we remember that the height of the pulse-wave is a linear measurement, while the strength of the pulse is a complicated one, represented by the formula $\frac{M.v^2}{2}$, in which v is the velocity of the ascending limb of the curve and M the mass of blood acting upon the finger during a pulse-beat. It, therefore, seems important to rehabilitate this primitive conception, which is the most correct and clear of all theoretic considerations in reference to the pulse.

As to how far we may go in deducing conclusions from the radial pulse in reference to the total work done by the heart, we would refer the reader to the chapter upon Sphygmobolometry. From the explanations which will be made of the technic of sphygmobolometry it also follows that palpation gives the most correct estimation of pulse energy when the artery is completely closed peripherally by one finger of the left hand, and pressure is made proximally by the palpating finger, as in the previously described static method (see p. 117), until the maximum pulse is obtained. Under these conditions the strength of the pulse-beat represents the energy of the pulse. The author would differentiate this from the previous methods of palpating the pulse by designating it as *the energetic method*.

Dicrotic Pulse.—We speak of a pulse as being dicrotic when a second wave follows immediately after the principal rise. (The nature of this will be discussed under Sphygmography, p. 130 et seq., and p. 146 et seq.) A dicrotic pulse furnishes a certain sense of after-beating to the palpating finger. It is usually associated with diminution of the minimum pressure. Both the primary and the secondary wave are felt to be greatest when the palpating finger presses only lightly; therefore a dicrotic pulse is best appreciated with gentle pressure. This can be readily understood from the explanation given of the excursion of the arteries (p. 117 et seq.). The beginner is apt to employ too great pressure to recognize such a condition readily.

It should also be noted that, upon the one hand, dicrotism may be simulated by early extrasystoles, while, upon the other, it may simulate

a pulsus bigeminus or a pulsus alternans. (See Fig. 63, p. 142.) This error may be prevented by simultaneous auscultation of the heart, which will determine the number of cardiac systoles.

Combined Qualities of the Individual Pulse.—We have a number of terms which refer to a pulse which comprises two or more of the qualities already described. Of these, we shall mention only those in most common use: pulsus fortis, strong pulse = large + tense (corresponding in quality to a pulse of great energy, see p. 118); pulsus plenus, full pulse = large and medium hard; pulsus debilis s. inanis, weak or feeble pulse = small + weak; pulsus undosus = large + soft; pulsus serratus = large + tense + rapid; pulsus vibrans = very large + very tense. This name is applied because the so-called elasticity elevations (see p. 130) may be distinctly appreciated by palpation. These terms are fitting enough, but rather unnecessary. Instead of employing them, it is better for a beginner to mention the individual qualities one after another. The Latin terms are sometimes combined. For instance, we speak of a pulsus tardodicrotus or a pulsus magnodurus, etc. Such combination terms are practical enough in themselves, but some of them are not sufficiently clear, considering the double meaning of the terms “celerity” and “tension” (see above). In general a detailed description is better than an attempt to describe the pulse by one word.

Further consideration of the significance of the qualities of the pulse will be taken up in conjunction with sphygmography, because some details may be certainly obtained and explained only by means of this method. This is particularly true of certain complicated peculiarities having most to do with changes in the pulse rhythm.

SPHYGMOGRAPHY

Sphygmography is the method of registering the pulse-wave of some peripheral vessel, generally the radial artery, upon a moving surface (usually smoked paper), by means of a special instrument, the sphygmograph.

INSTRUMENTS

Vierordt constructed the first sphygmograph, and since then a great many improved instruments have appeared. Most of them, however, have retained Vierordt's principle of transmission by means of a lever. The best known and most frequently employed sphygmographs are: Marey's, for a long time the only one used clinically; Landois', Sommerbrodt's, Riegel's, Dudgeon's, Jaquet's, and v. Frey's. Dudgeon's apparatus has been a favorite, because with it curves of considerable excursion are easily traced. Recently it has been discredited on account of the marked tendency to extensive swinging of the registering lever; but if we are not concerned with the form of the individual pulse-waves, it may be employed in the analysis of pulse-arrhythmia. (See p. 155.) Mackenzie has also adopted it for his polygraph (Fig. 52, p. 129). It possesses the same advantage as Jaquet's sphygmograph in that extended series of pulses may be recorded upon long strips of paper; but the latter is an improvement and includes a really excellent mechanism for marking intervals of time.

v. Frey's sphygmograph,¹ also a very excellent instrument, is depicted in Fig. 44. It possesses this advantage over other instruments: the motions of the pulse are transmitted to the writing-lever as simply as possible. The method of employing this instrument is as follows: The most superficial part of the radial artery is marked upon the wrist with a skin-pencil, and the apparatus is adjusted so that the "pelotte" impinges exactly over the indicated artery, and with the drum toward the elbow. It is then fastened to the forearm by means of the carrier or slide, *S*, with a strap.

Fig. 44.—v. Frey's sphygmograph.

The carrier (Fig. 45) is fastened separately with the hooks that are attached for this purpose. The screw *Sch* serves to fix the strap. Loosening screw 2 makes it possible to move the entire apparatus upon the "carrier." This is very convenient for the purpose of adjusting the "pelotte" more accurately. By means of screw 3 we attempt to regulate the amount of pressure upon the pad until the lever needle begins to make excursions. The apparatus is then firmly fixed in place by tightening screw 2.

Fig. 45.—The carrier or slide of v. Frey's sphygmograph.

The drum has, of course, been removed from the apparatus before this, covered with wax paper, smoked² by revolving over a flame, and then replaced upon the clock mechanism, *U*. By turning key 1 the drum can be moved so that the bent

¹ v. Frey, *Die Untersuchung des Pulses*, Berlin, 1892, J. Springer

² A pointed gas-flame is perhaps the best source for smoking, or a kerosene lamp without a chimney, or a piece of burning camphor. We must be careful not to smoke too thickly, because the friction between the registering needle and the drum would then be so great that the curve would be disturbed.

point of the registering needle rests lightly upon the smoked paper. The height of its excursion and, hence, of the curve can be regulated by turning screw 3, which controls the tension of the "pelotte." The clockwork is then started by means of the lever which is visible behind the writing-lever *H*, to the right of the drum. The drum revolves, and the bent point of the needle registers the sphygmographic curve upon the smoked drum. The drum is then taken off again, the paper carefully cut off, separated from the drum, and fixed in a 5 to 10 per cent. alcoholic solution of shellac or in a 10 per cent. solution of dammar balsam in benzin. The part *E*, which has not yet been described, is a small electromagnet with a registering needle attached to the armature, so that it registers upon the drum. When connected with an electric current, intervals of time or signals may be indicated in the same way as is customary in physiologic experiments. When not being used, it may be disconnected.

Von Frey has since modified his sphygmograph—and, it would seem, very advantageously. The chief improvement is the substitution of a delicate metal spring for the joint connections, so that the motions of the registering needle are less angular. Besides this, the drum is connected with a Jaquet's chronometer works, so that the time intervals are pictured. The curve may, of course, be registered by means of air transmissions upon a kymographion placed at some distance.

Jaquet's sphygmograph¹ (Fig. 46) consists of a metal frame, *D—p*, to which is sewed a cuff, *B, B*, for attaching to the wrist. The sphygmograph proper, *A—r*, is attached to the frame. The window cut out of the frame is to be applied accurately along the radial artery (previously marked out with a pencil), and the cuff then strapped around the wrist quite tightly. The sphygmograph proper is set into the frame by hooking into the hinge, *p*; and then the connection of the two parts is effected by pressing down at *r* and tightening the screw *m*. The pulse-registering apparatus consists of a short, broad spring, which presses upon the artery and transmits its movements to the registering needle by means of the lever system *d e f*. The screw *m* also serves to adjust the registering needle at the desired height upon the smoked strip of paper. By screwing it down, the spring *d* is pressed against the artery. The screw *c* is connected with an "eccentric" contrived to increase or diminish the pressure upon the spring. The amount of pressure can be determined by noting the position of the figures upon the screw. For the rules in reference to the amount of pressure or to the desired height of the curves see p. 140 et seq. With this mechanism the instrument can be adjusted with practically equal pressure in each case, and taken away from the frame and reapplied in the same case without alteration of the pressure. Jaquet's instrument, like Dudgeon's, writes upon a flat and not, as most other sphygmographs do, upon a curved surface. Another advantage consists in the very slight and constant amount of friction between the writing-needle and the paper, so that there is very little trouble in adjusting the registering part of the apparatus. The paper lies horizontally; it need not be especially strong, and it may easily be 40 or 50 cm. long. The little box *a* contains the clockwork which moves the strip of paper, *p*. This is started by pressing down on lever *b*. The rate at which the paper moves may be increased from 1 to 4 cm. per second by altering the position of lever *a*. The slower motion produces a curve which presents a better general idea; the more rapid motion, one which may be more accurately analyzed. This rate of motion may be altered while the sphygmograph is in action. The box *a* also contains a stop-watch device connected with the time-registering mechanism, *S*. The latter consists of a small pen which registers a mark upon the margin of the smoked ribbon every fifth of a second (Fig. 54).

The old style of the Jaquet sphygmograph, illustrated in Fig. 46, has the disadvantage that the individual parts of the pulse-registering mechanism are not connected firmly enough to insure their constant contact with every change in the rate of motion. At *e* and *d* the movements of the lever system are transmitted by loose joints. This is not a disadvantage when the excursions are slow, since the parts are held in contact by the metallic ball which is visible at the top of the apparatus. When the excursions are rapid (increased frequency of the pulse, great elevation of the pulse), however, the oscillations of this mechanism may give rise to errors. These consist particularly of the appearance of artificial elevations in the pulse curve, dependent entirely upon the apparatus. One part of the lever system may advance independently until it meets with resistance; then, at the moment of the occurrence

¹ Described in *Zeit. f. Biol.*, vol. xxviii, N. F., x. Manufactured by Schüle, at that time Mechanic to Physiologic Institute of Basel, now Director of the Institute for Scientific Chronometry, previously at St. Imier, Canton Bern, but since April 1, 1907, at St. Johannring, 26, Basel, Switzerland.

of this resistance, there is a jolt of the writing-lever, which appears as an artificial elevation in the curve, corresponding to nothing whatever in the pulse-wave. In addition to the occurrence of these artificial elevations, the oscillation dependent upon the defective connections of the parts of the lever system also causes an increase in the height of the curve. As we shall subsequently learn (p. 141), it is difficult under any circumstances to gain an idea of the volume of the pulse from the height of the curve, and this error of oscillation renders the employment of the sphygmograph for this purpose still more questionable. A further source of error is the fact that the rate of motion of the needle at the moment when the individual parts of the lever system are not in contact is dependent upon the weight of the small metallic

Fig. 46.—Jaquet's sphygmochronograph (old style).

ball. Jaquet himself has criticized these faults of his apparatus, which he copied from the Dudgeon sphygmograph, and has recently attempted to overcome them by a rearrangement of the recording mechanism, of which he gives the following description,¹ and the accompanying diagrammatic drawing (Fig. 47): "The movements of the pelotte (spring *a*) are transmitted to the bent lever *c c* by means of a wedge-shaped blade, *b*. The upper extremity of the bent lever is marked at *s* by a carefully made screw-thread which works in a corresponding cog-wheel, bearing the writing-lever. The contact between the screw thread and the cog-wheel is insured by a spring, *e*, which constantly presses the lever *c c* against the cog-wheel. In addition to this the bent lever *c c* does not turn upon an axis passing through its

¹ Münch. med. Woch., 1902, No. 2.

angle, as in the old instrument, but about the point *f*, and the axis of rotation is replaced by a short, flat watch-spring which insures the contact between the lever *c* and the edge *b*. This spring is so short that individual oscillations are not to be feared, since the length of such an oscillation is less than $\frac{1}{50}$ of a second, and is consequently trivial in comparison to the velocity of the pulse-registering mechanism. This spring also renders unnecessary the eccentric of the old instrument, since its

Fig. 47.—Diagram to explain the improved mechanism in the registering lever of Jaquet's sphygmograph.

tension is sufficient to overcome the resistance which the stretched skin offers to contact with the pulsating artery. The ratio of transmission in the short arm of the lever *c c* is 1:2, and that between the cog-wheel and the writing-lever 1:50, so that the total enlargement amounts to 1:100."

An artificial pulse has been constructed by Langendorff, upon a principle first employed by Donders, in which a revolving eccentric transmits to the pin of the sphygmograph excursions similar to those of an arterial pulse. Jaquet, by the use of this mechanism, found that his modified sphygmograph records the movements of the pulse accurately and without oscillation for all of the velocities usually encountered in sphygmography.

In spite of the marked improvements obtained by these changes, it seemed to the author that the construction of the modified Jaquet sphygmograph was still open to some objections, and particularly because there was not a firm connection between the blade *b* and the lever arm *c* (Fig. 47); if the velocity was very great or the pulse-rate very rapid, the parts *c* and *b* became separated, and thus still produced artificial elevations in the curve. The oscillating pad was a further disadvantage of the old instrument which had not been overcome in the new modification. In both the old and the improved models this pad was connected to the spring *a b* by a loose joint. This naturally simplified the application of the spring to the artery, but from the lack of a firm connection it also produced distortions of the curve. In order to obviate these faults Schüle, who made the improvements in Jaquet's modified sphygmograph, has, at the author's suggestion, attached the pad firmly to the spring, as in Marey's and v. Frey's sphygmographs, and also connected the arm *f c* of the bent lever with the blade *b* by a small wire stirrup, which passes over the lever from the edge of the blade, so that any separation of the blade and the lever is rendered impossible. This mechanism, recommended to the author by Schüle, acts like a hinge joint, but possesses none of its disadvantages. By these modifications the entire lever system has been united into a firm whole, in which no displacement is possible without implicating the entire system, and which must consequently accurately represent the movements of the arterial wall, disregarding the possibility of the oscillation of the entire system, a condition that the author has been able to exclude, for the velocities ordinarily encountered in sphygmography, by tests with Donders' artificial pulse. The jointed connection of the edge with the bent lever has the additional advantage that we may employ the eccentric of the original apparatus, which the author sorely missed in the improved Jaquet sphygmograph, since it not only greatly facilitated the application of the sphygmograph and rendered possible the necessary variations in the tension of the spring, but also permitted us to obtain in every pulse-tracing exactly the same amount of tension of the spring with the same position of the pencil. The writer believes that Jaquet's sphygmograph, with these different improvements, now answers all reasonable requirements. It, of course, produces lower curves than the old model, on account of the suppression of oscillation. The Institute for Scientific Chronometry, James Jaquet, A. G., previously in St. Imier, now in Basel, adds the described improvements to the old Jaquet sphygmograph for 28 to 35 francs, according to the condition of the instrument, and also furnishes the modified sphygmograph at the original price of 165 francs. This firm has constructed an additional model (Model I), which differs from the original in that all the lever connections are hinge joints and consequently less sensitive to misuse. Model I is now supplied unless a special request is made for Model II, which possesses the author's modifications above described.

Even those observers who recognize that low pulse-curves are truer to nature may sometimes wish to produce a curve of larger excursions, particularly when the pulse is small and weak, or when information is desired in reference to rhythm rather than to the form of the curve. This firm has consequently constructed for the author a third model, in which the excursions of the curve may be varied at pleasure. On account of technical difficulties this is effected, not by changes in the lever enlarge-

ment, but by a modification of the strength of the spring in the pelotte. With a pulse of constant energy, the stronger the spring, the less will be the excursion of the writing-lever, so that by changing the strength of this spring we may modify the height of the curve precisely as if we changed the length of the arm of the lever. As a matter of fact, this principle is employed up to a certain point in the accurate application of the ordinary Jaquet's sphygmograph. In this third model, the original tension of the spring is different, and by means of an eccentric the tension may be varied to suit any individual case. This change in tension is brought about by a sliding mechanism which moves downward toward the free end of the spring and thus shortens its working length. The author is convinced that by means of this mechanism the height of the curve may be varied throughout a most extensive scale. In order that the purpose of this mechanism be not misunderstood, it should be noted that the tension of the spring is not supposed to be varied with each record, since this is superfluous and unnecessarily complicates the technic. The mechanism simply makes it possible for those who desire high curves to set their sphygmographs permanently with a "long spring," while those who prefer a reduced height of the curve, and the lessened tendency to jolting, may work with a "short" or "medium" length spring. In fact, the mechanism should always be employed with a constant tension

Fig. 48.—Appliance for fixation of Jaquet's sphygmograph.

when it is desired to compare the records of different curves, particularly in reference to the maximum height obtained, since, if the tension of the spring be varied as well as the eccentric and the setting-screw, the conditions become so complicated that the possibility of comparison is lost. This fact naturally does not forbid utilizing a change of tension of the spring as a third aid in obtaining a record in a particularly difficult case. This form of the sphygmograph is supplied by the manufactory as Jaquet's Sphygmograph, Model No. III, with variable spring tension.

At the author's suggestion, the manufacturers attach the base of the new Jaquet's sphygmograph to a movable padded metal frame, in order to avoid compressing the artery by the ground-plate of the sphygmograph when the mechanism is firmly applied. This metal strap forces the artery upward to a certain extent and bridges it over above the pelotte.

F. Runne's laboratory in Heidelberg, for the manufacture of instruments of precision, has recently constructed a very practical appliance for the fixation of Jaquet's sphygmograph by means of which the instrument may be applied without any circular constriction whatever. Fig. 48 clearly shows its application, and requires no description except that the screw *g* replaces the setting screw of the original sphygmograph, since it presses the pelotte upon the artery by leverage.

The Employment of Jaquet's Sphygmograph as a Small Clinical Kymograph.—If it be desired to make graphic records of any kind (from a pen attached to a float,

for example) upon a vertical writing surface, any of the kymographic appliances may be employed. If such a mechanism cannot be obtained, the appliance illustrated in Fig. 49 may be utilized. It was constructed for the author by the manufacturers of the Jaquet sphygmograph. It consists of a long plate, which is provided with a double row of small rollers, as shown in the illustration, which guarantee an accurate movement of the paper strip of the sphygmograph, even in the vertical position. The sphygmograph itself is attached in the middle of this plate (Fig. 49), and serves simply as a motor for the strip of paper, while the writing appliance employed may vary (Marey's air-cushion, a pen attached to a float, etc.). The time-registering mechanism of the sphygmograph may also be employed in this position. In such experiments the strip of paper is quite narrow, and to adjust it to the proper height

Fig. 49.—Jaquet's sphygmograph used as a kymograph.

the sphygmograph and its plate are fastened to a vertical rod by a sliding attachment. This appliance was used by the author for his sphygmobolometric records before he constructed the simple writing mechanism of the present sphygmobolometer. The curves depicted in Fig. 7 in his original work upon sphygmobolometry (p. 175) were recorded in this manner.

INSTRUMENTS FOR THE SIMULTANEOUS REGISTRATION OF THE ARTERIAL PULSE AND OF OTHER PHENOMENA OF MOTION

JAQUET'S CARDIOSPHYGMOGRAPH (Fig. 50)

We are indebted to Jaquet for the construction of an instrument designated as the cardiosphygmograph, which makes it possible to obtain upon a single broad

strip of smoked paper the radial pulse, together with two other phenomena of movement, such as the apex-beat, the carotid pulse, the venous pulse, the liver pulsations, or the respiratory excursions. This instrument is depicted in Fig. 50.¹ The three curves are recorded in a parallel manner, as shown in the illustration. For additional clearness the curves are depicted in black upon a white background in the figure, while the opposite condition obtains in the actual mechanism. The instrument, as a whole, corresponds in its construction to that of Jaquet's sphygmograph (Fig. 46, p. 123), but with the difference that two pneumatic registering appliances, *E E*, are added to the direct recording mechanism for the radial pulse. It is consequently larger, but nevertheless easily transportable. Like Jaquet's sphygmograph, the cardiosphygmograph is also provided with excellent clockworks, *A*, which mark fifths of a second upon the strip of paper by means of the writing mechanism *a*. This apparatus is also supplied with the metal frame recommended by the author (p. 125), which protects the radial artery from the pressure of the base of the instrument when it is buckled about the wrist. In the newer instruments the loose connections between the sphygmograph spring and the writing-lever are replaced by firm ones, in accordance with the principles stated upon p. 124 et seq., and the

Fig. 50.—Jaquet's cardiosphygmograph.

small spherical ball depicted above *e* in the illustration is consequently omitted. The connections are made by hinge-joints, as in Jaquet's sphygmograph, Model I (p. 124), and there is also a similar connection between the air-cushion (*pelotte*) and the writing-lever. The arresting mechanism, *b, c, d*, is attached to an axis which may be rotated by the lever *e*, thus raising the three writing points while the strip of paper is introduced. Upon the posterior surface of the apparatus, partly visible in the figure, are found the openings by means of which the writing drums *E E* are connected by tubes with the pneumatic recording appliances. The remaining parts of the apparatus will be sufficiently understood from the figure and from the description of the sphygmograph on p. 122 et seq. The rubber membranes of the writing-cushions may be easily replaced when damaged; the best material for this purpose is the rubber membrane employed in the preparation of the desmoid capsules (See Examination of the Stomach.) In the directions for use accompanying the instrument are found the necessary instructions for the manipulations required in changing the membranes. In most cases, particularly for the carotid

¹ This instrument may be obtained from the firm of James Jaquet, Institute for Scientific Chronometry, A. G., Basel, St. Johannring, 26.

pulse, the venous pulse, the hepatic pulsations, and even for the apex-beat (see Cardiogram) and the respiration (see p. 100 et seq.), small glass funnels may be employed as pneumatic receivers. The size of the funnels must be varied with the individual case, but generally it is well to employ the smallest funnel possible. These funnels are attached to the free ends of the tubes connected with the writing drums, and they are then held in air-tight connection with the part of the body selected while the curves are being recorded. The length of the tubes is immaterial, since the pulsating variations in pressure are transmitted through air with the same velocity as sound. For recording the apex-beat Jaquet has constructed a special receiving appliance, which is described and illustrated in the section upon Cardiography.

At the author's request Jaquet's sphygmocardiograph has recently been combined with an appliance for the graphic marking of the cardiac sounds, and this instrument is supplied by the manufacturers in reduced form as the "Simplified Jaquet's Sphygmograph" (Fig. 51)

This model differs from that depicted in Fig. 50, in that the direct writing sphygmograph lever is connected with but a single pneumatic recording mechanism.

Fig. 51 —Simplified Jaquet's sphygmograph.

This instrument is, therefore, not only cheaper, but more compact and easier to manipulate; if the directions upon pp. 152 et seq. and p. 193 be followed, three or even more movements may be chronometrically compared with one another, although but two curves can be recorded simultaneously. For further information in reference to technic and to the significance of simultaneous records the reader is referred to p. 152 et seq. and p. 193, and also to the chapter upon Cardiography. This simplified cardiosphygmograph is also well adapted to the acoustic marking of the cardiac sounds, and to the recording of pneumatic signals upon sphygmographic curves, as is done in the determination of the minimum arterial pressure (p. 174).

The *Mackenzie polygraph* (Fig. 52) fulfills the same purpose as Jaquet's simplified sphygmograph, since it directly records the radial pulse and pneumatically records a second movement (carotid pulse, venous pulse, apex-beat, respiration, etc.). The sphygmograph employed in this instrument is Dudgeon's (p. 120). The pneumatic compartment, constructed like the ordinary Marey's drum, may be inserted at the point *b* in a movable upright.

This appliance has also been utilized by the author for the acoustic marking of

the cardiac sounds and for the recording of signals in the determination of the minimum arterial pressure (p. 174). In the figure is depicted one of the beaker-like receiving appliances, such as is employed by Mackenzie, instead of the small glass funnel. For the recording of hepatic pulsations Mackenzie employs a similar receiving appliance of larger size, which is pressed deeply into the hepatic region. In order that the writing-lever be not elevated too far above the writing surface,

Fig. 52.—Mackenzie's polygraph and recording mechanism.

the larger receiver is provided with a lateral opening, which is left open when the receiver is pressed against the area in order to let the air escape, and then closed with the finger during the recording of the curve.

SIGNIFICANCE OF A NORMAL PULSE-CURVE; FACTORS WHICH INFLUENCE ITS FORM

The curves obtained with the good modern sphygmographs usually correspond quite uniformly. Fig. 53 represents a normal pulse-curve of the radial, the artery which is commonly selected. This illustrates what we have already learned from palpation, that the pulse-wave is composed of a steep ascending and a rather slanting descending limb. Palpation alone might lead us to believe that the ascending and descending limbs of the wave present smooth lines, but sphygmographic tracings show a number of small elevations in the descending limb (so-called *catacrotic* elevations). Similar irregularities which may appear under pathologic conditions in the ascending limb are termed *anacrotic* elevations. A pulse with *catacrotic* elevations is termed *catacrotic*; one with *anacrotic* elevations, *anacrotic*.

The normal pulse has usually three distinct *catacrotic* elevations, and is therefore *catatritic*. The significance of the individual parts of the pulse-curve, especially of these elevations, has created much discussion. Marey and Landois, and recently Hürthle, v. Frey, and Krehl, have taken the most active part.

To understand the pulse-curve we must, first of all, avoid confusing the progressive motion of the blood with the wave motion. This difference is very clearly illustrated by E. H. Weber's well-known expression, "*Unda non est materia progrediens sed forma materiae progrediens.*"

In palpating a pulse or in employing a sphygmograph we study exclusively the wave motion of the blood. Of course, the wave motion has some connection with the conditions of the blood-current, but only

indirectly. The pulse of a peripheral artery is a wave motion which has reached this vessel by transmission to the periphery of the primary wave arising in the aorta, long before the blood whose impulse produced the primary aortic wave has reached the artery. The rate of transmission of the wave motion of the blood is quite rapid—according to E. H. Weber about 9 m. a second. As we should expect, from what has just been said, an aortic curve (from an animal) corresponds very closely to the human radial curve. It rises quickly, and falls off gradually with secondary waves and depressions. To understand the radial curve thoroughly, it is well to begin by analyzing the aortic curve. The wave motion in the aorta is evidently due to the fact that during the “expulsion period” of systole the blood-content of the aorta is increased. Afterward, when the aortic valve has closed, this increase is carried toward the periphery by the increased tension of the aortic wall. Thus the ascending limb of the aortic curve evidently corresponds in general to the so-called “expulsion time,” *i. e.*, the period during which blood flows from the heart into the aorta. The summit of the pulse-curve, however, does not correspond exactly to the end of the “expulsion time,” *i. e.*, to the closure of the semilunar valves. On the contrary, the “expulsion time” is probably extended over into a part of the descending arm of the curve, because the flow of blood into the aorta is

Fig. 53.—The normal radial pulse-curve (Riegel).

being diminished, so that the aorta is being partially emptied toward the periphery all the time. The end of systole is, then, not marked in a pulse-curve, but lies in the descending limb of the curve, somewhere near the summit. The descending limb of the curve thus includes this remnant of the “expulsion time” plus the whole period during which the aortic valve is closed, *i. e.*, that part of systole which lasts after the close of the semilunar valves (Martius “persisting interval”); the whole of diastole; and the so-called “closure time” of systole.¹ Hence, the descending limb is more than diastolic; but for the sake of brevity it may be called diastolic.

The secondary elevation of the descending limb, which is designated *a* in Fig. 53, is usually distinguished from the others by being very distinctly marked. If it be still further developed, the pulse becomes dicrotic. It is, therefore, called the “dicrotic elevation or wave,” and is generally considered to be a “recoil elevation,” coinciding with Landois’ theory of its origin, which, however, will not withstand criticism. His theory is as follows: At the moment when the primary positive wave leaves the aorta, *i. e.*, when the stretched aortic wall, in virtue of its elasticity, retracts again, this elastic retraction exerts an impulse upon the column of blood. This impulse strikes the closed aortic valve, is reflected back, and passes through the aorta centrifugally

¹[See Robinson and Draper, “The Presphygmie Period of the Heart,” *Arch. Int. Med.*, 1910, vol. v, No. 2, p. 168.—Ed.]

to all the peripheral vessels in the form of a second positive pressure wave. In cases where the duration of each pulse-wave is sufficiently long for a complete formation of the pulse-curve, the recoil wave may, in its turn, according to Landois, produce another second recoil wave. This second recoil elevation may be recognized by the fact that it follows about as quickly after the recoil elevation as the latter did after the primary wave.

Landois considers that *b* and *c* (Fig. 53), which are smaller elevations, are elasticity elevations, *i. e.*, due to individual vibrations of the arterial wall which are not transmitted from the blood-column to the arterial wall, but, conversely, from the arterial wall to the blood-column. (See p. 132 et seq. for a criticism of this conception of the secondary elevations.)

From experiments with rubber tubes Landois¹ states the following laws governing both kinds of secondary elevations:

1. The further the artery is from the heart, the later the recoil elevation appears in the diastolic portion of the curve.

2. In the same artery, the further from the heart we apply the sphygmograph, the less pronounced is the recoil elevation.

3. The recoil elevation is so much the more pronounced at the heart the shorter (sharper) the primary wave, and vice versa. The duration of the primary wave being equal, one of large volume produces a stronger recoil wave than one of small volume. If, however, such a large voluminous wave persist for some time, while a small wave last only a short time, the latter will produce the larger recoil elevation. The deciding factor is thus always the brevity, *i. e.*, the celerity of the primary wave.

4. Other things being equal, the recoil elevation is larger the lower the mean arterial pressure.²

5. The further the examined artery is from the heart, the more marked are the elasticity elevations in the descending limb of the curve.

6. An accentuation of the mean pressure in the artery will increase the number of the elasticity elevations upon the descending limb, and at the same time bring them nearer the summit of the curve.

7. When the mean blood-pressure is very low, the elasticity elevations disappear entirely.

8. In diseases of the vessels which affect or destroy the elasticity of the artery, the elasticity elevations are either much diminished or else disappear entirely.

The following assertions may be ventured in regard to the varying shapes of the entire curve.³ They are based partly upon experimental investigations by Marey, Landois, and others with tubes, and partly upon clinical observations:

1. Other things being equal (the same blood-pressure), the pulse-curve is higher the larger the systole, and vice versa.

2. Other things being equal (equal systole and equal blood-pressure), the ascending limb of the curve is steeper the more quickly systole takes place.

3. Other things being equal, a low mean blood-pressure produces both a steep ascent and a steep descent, *i. e.*, a pointed curve (celerity of curve *in toto*). Conversely, a high blood-pressure produces a slanting rise and gradual descent (tardiness of curve).

¹ Die Lehre vom Arterienpuls, 1872.

² Attention must here be called to the fact that while this is generally true, we are by no means always justified in assuming the existence of low blood-pressure from a distinct development of the so-called recoil elevation, better termed the dicrotic wave. The author was convinced of this by the following experiment upon a dog: A sphygmogram was made from the exposed femoral artery and the pressure in the other femoral artery simultaneously measured by a mercurial manometer directly connected with the vessel. The arterial pressure was enormously increased by an injection of strychnin, and in spite of this the sphygmogram exhibited the most pronounced dicrotism. The subsequently stated view of the limited clinical value of the form of the sphygmogram might be based upon this experiment.

³ A very good way of judging the real shape of a curve with many secondary elevations is to bisect each secondary elevation and then join the points by a dotted line, as in Fig. 54.

4. Other things being equal, rigid arterial walls (like high blood-pressure) produce low curves with slanting ascent and gradual descent (tardiness). On the contrary, delicate elastic arteries (like low blood-pressure) produce curves with steep ascents and descents (celerity).

As a matter of clinical experience, however, it must be acknowledged that only the descending limb of the curve is affected by either arterial rigidity or blood-pressure, for the great working capacity of the heart is sufficient to make the rise of the curve steep even with rigid arteries and with a high blood-pressure. All these statements possess more theoretic than diagnostic interest.

Anacrotic elevations occur only under pathologic conditions. Landois has come to the following conclusions concerning them:

Anacrotic elevations, i. e., secondary elevations in the ascending limb of the curve (Fig. 68), are elasticity elevations. They depend upon influences similar to those which cause the ordinary elasticity elevations of the descending limb. The reason that anacrotic elasticity elevations are so rarely observed is because, as a rule, the ascending limb is so steep that elasticity elevations could not be reproduced in it. Hence, all the factors which tend to retard the rise of the curve are capable of producing anacrotic elevations, especially when these factors referred to also favor the formation of elasticity rises. (See above and p. 148.)

The shape of the curve is decidedly influenced by the frequency of the cardiac action, because a quick sequence of the chief wave makes a complete formation of secondary waves in the descending limb impossible. At the moment that the systolic rise of a new wave begins, all secondary elevations disappear in the great rise

Fig. 54.—Reduction of a sphygmogram to its simplest form. The above curve was taken with a Jaquet's instrument, the four waves at the left while the paper was moving slowly; the three at the right while moving rapidly. The time intervals are shown in the notched line above (0.2 second).

of the new wave; although otherwise they would have developed in the descending limb of the preceding wave. Curves with a slow sequence of beats are, therefore, generally richer in secondary elevations. An illustration of the action of the frequency of beats upon the pulse-wave is the change of a febrile dicrotism of the pulse to hyperdicrotism and to monocrotism. (See Fig. 70.)

Although these facts are essentially correct, the explanations mentioned are not necessarily so, and they consequently do not possess any considerable clinical value, because, as stated in the preceding paragraphs, the form of the sphygmogram always depends upon different factors which, clinically, cannot be sufficiently analyzed. All these statements, however, are still encountered in the literature and are responsible for false deductions from the sphygmogram. Landois' explanation of the secondary elevations favors such false deductions, for it is incorrect, although not generally recognized. Von Frey and Krehl disproved it. These investigators studied the pressure curve by an artificially produced current impulse upon an aorta (left *in situ*) in a recently killed animal. They registered simultaneously the manometric pressure curve from the beginning of the aorta and from the celiac axis. A detailed examination showed that each individual secondary elevation may be explained by the fact that the primarily produced variations in pressure are reflected, as it were, from the periphery to the center and then back again to the periphery. Under certain conditions they may traverse

this path repeatedly in the curve. According to this there are neither recoil nor elasticity elevations; the so-called waves (even the anacrotic elevations) are nothing more than centripetal or centrifugal reflections of the principal wave, which interfere with it in various ways as well as with one another. Von Frey and Krehl claim that these elevations, and especially the dicrotic rise in every vascular area, are due to centripetal and centrifugal impulses, but in different and complicated ways. They characterize the dicrotic rise practically as a reflected wave which arises late, and which is, therefore, very distinctly marked from the main wave; whereas, they characterize the so-called elasticity waves which precede the dicrotic rise merely as waves derived by reflection of the main wave from points closer together, so that they are partly confluent with the main wave. Further, they characterize the elasticity elevations which come after the dicrotic rise as waves of reflection, like the latter, but arriving late and becoming less and less distinct toward the end of the curve, because the distance they traverse progressively increases.

According to these views, which are undoubtedly correct, the terms "recoil" and "elasticity elevations" must finally be omitted from clinical terminology, just as was the case with the expression "valve-closure elevation," which also depended upon a false conception, and has now happily disappeared from the literature. Because these designations are still current in the literature, and because their present omission would result in confusion in a general book such as this, they are retained here, much to the author's regret.

The next question is, will these theories explain the relationship between the height of the blood-pressure and the so-called elasticity elevations and the dicrotic waves—a relationship which possesses a certain although a limited importance? But von Frey and Krehl found that an increase of the blood-pressure pushed the reflected waves nearer to the main summit of the curve (*i. e.*, in the sense of time), because the rate of transmission of the waves increases with the blood-pressure. This explains the fact that those reflection waves which are situated nearest to the main summit (which are ordinarily described as elasticity elevations), and which include the anacrotic elevations, occur chiefly when the blood-pressure is high. It also explains the fact that with a low blood-pressure a reflection wave occurs as a so-called dicrotic wave arriving very late and characterized by being very distinctly formed, because at this moment the tension of the arterial wall is low enough for the wall to make quite a marked excursion. So we see that, as a matter of fact, these relations between blood-pressure and the form of the curve may be explained by the theory of the reflection of the secondary elevation.

The Negative Sphygmogram as a Source of Error

A comparatively little known source of error in sphygmography, to which Mackenzie¹ first called attention, is that an inverted curve is sometimes obtained.

Correct
sphygmogram

Negative
(inverted)
sphygmogram

Fig. 55.—Mackenzie's negative sphygmogram. Two curves taken from the carotid simultaneously. The receptor of the upper curve was upon the artery, that of the lower was laterally placed. The lower curve is almost the reverse of the upper one.

When the radial or carotid, for example, pursues a tortuous course, its form is so

¹ The Study of the Pulse, 1902.

changed at the moment of maximum pressure that the tortuosity is diminished and the artery consequently moves laterally. If the pelotte of the sphygmographic appliance be not exactly upon the middle of the artery, it can happen that the sphygmograph records this lateral movement instead of the blood-pressure, and if the pelotte be so placed that the artery is removed from its pressure by the pulse-wave, there may be produced what Mackenzie has designated as a *negative sphygmogram*. (See Fig. 55, which is a pronounced example.) It was formerly believed that such a plateau-shaped pulse was produced by too strong a tension of the spring or, as it was sometimes expressed, it was "mashed." This conception, however, is entirely erroneous.

The Influence of the Respiration Upon the Pulse-curve

To study the influence of the respiration upon the pulse-curve, it is necessary to have simultaneous graphic records of the radial pulse and of the respiration. The least complicated instrument for this purpose is the simplified Jaquet sphygmocardiograph, as depicted upon p. 128, a combination of the Jaquet sphygmograph with a pneumatic appliance by means of which another movement can be recorded upon the same strip of paper. The small funnel which serves as a pneumatic receptor (see p. 128) is applied either to the jugulum or to the supra-clavicular fossa. (See p. 100.)

It has long been known that deep breathing may have some influence upon the pulse-curve. This influence is chiefly due to the changes of arterial pressure which occur in the two phases of respiration. The respiratory increase in pressure manifests itself in a sphygmogram by an elevation of the whole curve¹ and by an alteration in the shape of the individual pulse (the latter corresponds to what was said in 4 and 6, p. 131 et seq.), viz., a diminution of the dicrotic rise, an increase of the elasticity elevations.

Authors differ very materially, however, as to whether the variations in pressure which are evident in a sphygmographic tracing belong to inspiration or to expiration. The reason for such a difference of opinion is that the factors which alter the blood-pressure during respiration are manifold; they frequently produce opposing results, and the final effect varies according to the way that the breathing progresses. The most important influence of breathing upon the blood-pressure is probably to be found in the change of diameter of the pulmonary vessels. They become wider during active inspiration and narrower during expiration.²

Consequently, so long as the dilating pulmonary vessels receive an excess of blood at the beginning of inspiration, the greater circulation must receive less blood (because the size of the diastole, and with it that of the systole, is diminished), and so the blood-pressure will fall. However, in the second part of inspiration the pulmonary circulation through the dilated pulmonary vessels improves; this in turn favors both diastole and systole, and eventually the greater circulation, and so increases the blood-pressure. During expiration the reverse occurs. The pulmonary vessels become narrower; they therefore empty a part of their blood into the greater circulation; the diastole and the systole of the left heart become fuller and the pressure increases. As soon, however, as the pulmonary vessels have become empty, the increased resistance in the lung will be felt as a factor in diminishing the diastole of the left side, and the pressure in the general circulation will be reduced.

Therefore, under these conditions blood-pressure falls during the first half and increases during the second half of inspiration; whereas, conversely, pressure increases during the first half and diminishes during the second half of expiration. Hence, a maximum of pressure occurs at the beginning of expiration; a minimum, at the beginning of inspiration. These rules, however, apply only to very slow and deep breathing. Only the initial effect of the change of diameter of the pulmonary vessels is felt during rapid breathing, viz., expiration increases the pres-

¹ This sign is, however, ambiguous, because the pelotte of the sphygmograph rests not only upon the artery, but also upon the *venæ comites*, and, of course, any increased dilatation of the latter will also lift the registering-levers.

² The conditions differ in the case of the artificial respiration employed in animal experiments.

sure, inspiration diminishes it. Hence, respiration influences blood-pressure in two opposite ways, according to its rapidity. And especially in pathologic cases, where the breathing is abnormal, it is evident that the two types may be merged beyond recognition, so that we are unable to formulate any fixed rule for the relation of the sphygmogram to the respiratory phases. This is one of the causes for the diversity of opinion found in literature. As a matter of fact, we have considered only the most important factor by which respiration affects the arterial pressure, namely, the varying diameter of the pulmonary vessels, whereas in reality the conditions are much more complicated; for example, we might consider the influence of the varying intrathoracic pressure upon the heart and upon the great intrathoracic vessels, the effect of varying intra-abdominal pressure upon the vessels of the abdominal cavity, which changes with respiration, and further the changes of the vasomotor tonus synchronous with respiration. Nevertheless, it may be stated, as a rule, that in the sphygmographic tracing (Fig. 56) deep and slow breathing increases the pressure during inspiration and diminishes it during expiration; whereas deep and rapid breathing produces the reverse effect. The pulse frequency is often accelerated during inspiration. Corresponding to the mode of origin of the variations in pressure, the individual beats which coincide with the increase in pressure are greater than those which correspond to its decrease.¹

It should also be noted that the lower the arterial pressure, the more decided are the effects of respiratory influence upon the pulse-curve, since thoracic aspiration naturally causes a greater increase of arterial pressure when the arteries are

R

P

T

Fig. 56.—The influence of deep and slow breathing upon a normal pulse-curve: R, Respiration curve, inspiration upward; P, pulse-curve; T, time curve (intervals = 0.5 second) (Rollet).

comparatively empty than when they are markedly full. Such imperfect filling of the arteries generally, but not always, coincides with low pressure. Upon the other hand, with a low arterial pressure the arteries may be even abnormally distended, e. g., when the low pressure depends upon dilatation of the arteries with a good volume of circulating blood. Arterial pressure in itself is consequently not responsible for the occurrence of pronounced respiratory variations in the pulse-curve, but for the volume of blood contained in the arteries. To this extent the occurrence of marked inspiratory variations in the pulse-curve possesses a certain interest in our consideration of circulatory conditions.

It must always be borne in mind that the pulse-curve may be affected by abnormalities of breathing, for disregarding the previously mentioned effect of the frequency, the influence of respiration upon the pulse-curve is naturally more pronounced if the respiration produce great variations in intrathoracic pressure. As a result of this we observe particularly pronounced variations of the pulse-curve in stenoses of the air-passages and in all conditions, like pneumonia and pleurisy, in which the equalization of the intrathoracic and extrathoracic air pressures is disturbed.

Mackenzie (*loc. cit.*) gives two interesting examples of simultaneous records of the respiration and of the pulse (Figs. 57 and 58). Fig. 57 is a record in which the respiratory period accidentally corresponds in length with the period of a trigeminal pulse, so that without a simultaneous graphic record we might be led to suppose

¹ For further information see Tigerstedt, *Lehrbuch der Physiologie des Krieslaufes*, 1893, p. 453 et seq.

that the causal factor of the trigeminal pulse was to be found in the respiration. The simultaneous record shows, however, that the respiratory curve holds a constantly changing relation to the period of the trigeminal pulse, and such a direct causal relation may thus be excluded. Figs. 58 and 59, exhibit sphygmograms from the arm, in which the involuntary movements of the arm dependent upon respi-

dur
ode
beci
curve.

the
peri-
ver,
tory

ration simulate the influence of the respiration upon the pulse-curve. Fig. 58, which seems to demonstrate the marked influence of the respiration upon the pulse-curve, was taken when the arm was not fixed; Fig. 59 was recorded with the arm firmly fixed, and such influence is almost entirely wanting.

Respiration exerts a particularly pathologic influence upon the pulse-curve when, as the result of intrathoracic adhesions (particularly in the mediastinum),

Fig. 58.—Variations in the pulse synchronous with the respiration (copied from Mackenzie, Fig. 158, p. 164).

inspiration or expiration exerts an abnormal traction or pressure upon the veins leading to the heart, by which the blood is more or less withheld from the vessels during one of the respiratory phases (*pulsus paradoxus*, *cicatricial mediastinitis*, see p. 143 et seq.).

Besides the effects of the previously mentioned mechanical and direct influences upon the circulation, we must also bear in mind an indirect influence of the respira-

Fig. 59.—The same pulse with the arm fixed, copied from Mackenzie (Fig. 159, p. 164). The variations in the pulse which were synchronous with respiration have almost entirely disappeared. The variations in the pulse-curve are consequently largely dependent upon the movements of the arm associated with respiration.

tion upon the cardiac and vascular innervation. Certain disturbances of rhythm, such as the occurrence of extrasystoles, for example (see p. 154 et seq.), may consequently be associated with definite respiratory phases or at least repeat themselves in the respiratory tempo. Upon this point, however, there is little known. The case recorded in Fig. 57 also belongs under this head.

Under normal conditions the influence of respiration upon the pulse-curve is slight and scarcely perceptible even in the sphygmogram, so that when marked inspiratory variations are present in the pulse-curve, we should look for one of the above-mentioned pathologic factors.

OTHER FACTORS WHICH INFLUENCE THE PULSE-CURVE

1. Diminution of the amount of blood. This produces a diminution and a delay in the elasticity elevations and a decided prominence of the dicrotic wave. Phlebotomy may sometimes be sufficient to accomplish this effect.

2. An intermitting cardiac activity diminishes the arterial pressure during the intermission of the pulse. Consequently the pulse-wave following upon the pause presents signs of diminished pressure, i. e., the elasticity elevations are weaker and delayed and there is more pronounced dicrotism.

3. Elevating an extremity diminishes, depressing it increases, the arterial pressure in the part, as a result of the hydrostatic effect of the pressure of the column of blood in the particular artery. Consequently the sphygmogram of an elevated area shows more distinct dicrotism and slighter elasticity elevations than that of a horizontal or dependent area.

4. Compressing the larger vascular trunks produces an increase of pressure in the other pulsating vessels. This is shown in a well-known way by the sphygmogram.

5. An interference with the venous flow from an extremity acts in an opposite way. The arterial pressure in the supplying artery increases, and its sphygmogram is correspondingly altered. The rise of the curve as a whole is, however, partly due to the distention of the congested veins. (See p. 135, Note 2.)

Landois and Marey are responsible for most of these statements.

DIAGNOSTIC SIGNIFICANCE OF THE PULSE-CURVE

At first observers were naturally inclined to overestimate the value of sphygmographic tracings for the diagnosis of pathologic conditions, but to-day most clinicians have gone to the opposite extreme. As a matter of fact, sphygmography is more than an interesting amusement: it is really a valuable help in the interpretation of circulatory changes.

THE EMPLOYMENT OF THE CONTINUOUS TOTAL SPHYGMOGRAM

While many difficulties are encountered in drawing conclusions from the form of the individual pulse-curve in the sphygmogram, the employment of the pulse series therein is much less objectionable, as may be seen from the following sections upon the frequency and the rhythm of the pulse, from the "practical examples" (p. 149), and from the special section upon the analysis of the arrhythmic pulse (p. 152).

FREQUENCY OF THE PULSE IN THE SPHYGMOGRAM

With Jaquet's and with von Frey's latest sphygmograph, both of which are furnished with a time-marking apparatus, we can estimate the frequency of the pulse very accurately merely by the sphygmographic tracing. It should, nevertheless, be noted that in certain cases errors may occur in estimating the pulse frequency, even from the sphygmogram, unless auscultation, cardiography, and the recording of the venous pulse be also employed. Examples: Pseudobradycardia (see Bradycardia, p. 113 et seq.) and the pulsus pseudoalternans (Fig. 63, p. 142). The sphygmogram, best combined with the venous pulse tracing, is of especial importance in an explanatory analysis of such exceptional alterations in frequency as *tachycardia* and *bradycardia*. (See p. 157 et seq.)

RHYTHM OF THE PULSE IN THE SPHYGMOGRAM

A pulse-tracing shows the pulse rhythm at a glance, and much more accurately than it can be described. A *regular* pulse is one in which the individual waves follow each other at exactly equal intervals of time. Where this is not the case, the pulse is termed *irregular*. If the irregularity be complete, we call it a *pulsus irregularis*, without further comment. A *pulsus intermittens* is one in which, after a regular number of waves, one beat from time to time is omitted. A *pulsus intercidens* is one in which a small beat is inserted into a regular sequence of beats. The so-called *bigeminus* (Figs. 60 and 76) and *trigeminus* (Fig. 61) rep-

Fig. 60.—Pulsus bigeminus in typhoid fever; due to extrasystoles (Jaquet's sphygmograph, model II, p. 124).

resent periodically irregular pulses. In the former 2 beats, and in the latter 3 beats, are grouped together and separated from the preceding and following beats by a somewhat longer interval. Their curves usually do not reach the base line between the groups of 2 or 3 beats, so that the sphygmogram looks like a two- or three-peaked curve.

The designations just employed express only the apparent form of the pulse. With the exception of the failure of a pulse from disturbances of conduction (see p. 157 et seq.), auscultation demonstrates that the intermittent pulse is due to extrasystoles, i. e., to supernumerary systoles, brought about by abnormal or so-called extra stimuli, which are so closely approximated to the normal systoles that they do

Fig. 61.—Pulsus trigeminus equalis (after Riegel) (extrasystoles).

not produce a pulse in the peripheral artery, since at this time the heart is insufficiently filled. The *pulsus intercidens* is also to be regarded as an extrasystole introduced into a regular pulse-wave and transmitted to the periphery. Most instances of *pulsus bigeminus* and *trigeminus* (except the characteristic grouping from conduction disturbances, p. 157 et seq.) are likewise to be regarded as the result of extrasystoles, since one (*bigeminus*) or two (*trigeminus*) such extrasystoles are so interpolated into the main pulse that they are also apparent in the peripheral artery.

In reference to the occurrence of the different irregularities of rhythm see chapter upon the Modern Analysis of the Irregular Pulse (p. 152 et seq.). In reference to the

possibility of distinguishing a competent from an incompetent heart by making use of the sphygmographic form of the irregularity see p. 149 et seq., under Practical Examples.

THE EMPLOYMENT OF THE CURVE OF THE INDIVIDUAL PULSE

The chief difficulties in the interpretation of the sphygmogram are encountered in the curve of the individual pulse. The factors which influence the shape of the individual pulse-curve are so numerous (see p. 131 et seq.) that many different circulatory conditions may be responsible for an identical sphygmogram; so that even in a cardiac case we are not justified in making a diagnosis merely from the type of the curve. Even the curve of aortic insufficiency, one of the most characteristic of all curves, cannot be considered as pathognomonic of this affection; exactly the same type may occur without any valvular lesion. Still, the sphygmogram is valuable in the diagnosis of many conditions, provided that other symptoms are given their proper value, and provided that the clinician possesses considerable technical skill in making the tracings and a very accurate knowledge of the significance of the sphygmographic curve and of the way it may be modified by various factors. Such a knowledge can be obtained only by studying works upon physiology.¹

One of the main objections to making use of the curve of the individual pulse for diagnostic purposes has been that all the variations in this curve attributed upon p. 131 et seq. to the arterial tension in the aorta, *i. e.*, to general circulatory conditions, can be produced by local changes in the vasomotor tone of the artery. Of course, if this objection were correct, sphygmography would practically be relegated to a useless place. Mosso is chiefly responsible for this objection. He found that the pulse-curve could be changed by local thermic application, *e. g.*, the local application of heat to the arm dilates the vessels and produces a pulse-curve characteristic of low tension, while local cold produces a curve characteristic of high tension. But a closer examination of Mosso's curves shows that such changes are quantitatively quite insignificant, and apply much more to the height of the curve than to its shape. Variations in the pressure acting upon the vessels from without produce but an insignificant effect upon the shape of the pulse-curve. This Mosso easily determined in his investigations, which were made with a water sphygmograph. The author has become convinced that it is extremely difficult to alter very materially the shape of the individual beats by such local thermic influences, either in the sphygmogram or in the tachogram.² Besides, where the changes are pronounced, it is not possible to exclude the effect upon the general blood-pressure which can be produced reflexly by the local application of heat or cold. In fact, where the greatest alterations were observed the patients reacted to the thermic changes with sensations of heat and cold. The author has never been able to change a high tension to a dicrotic pulse, or the reverse, by purely local influences of so moderate

¹ Landois, *Die Lehre vom Arterienpuls*, 1872; Marey, *La Circulation du Sang*, 1881; Grashey, *Die Wellenbewegung elastischer Röhren und der Arterienpuls des Menschen*, Leipzig, F. C. W. Vogel, 1881; v. Frey, *Die Untersuchung des Pulses*, Berlin, J. Springer, 1892; Mosso, *Die Diagnostik des Pulses in Bezug auf die localen Veränderungen desselben*, Leipzig, Veit & Co., 1879.

² E. Balli, *Ueber den Einfluss von Erwärmung und Abkühlung der Haut auf das Flamentachogramm*, I. A. D., Bern, 1896.

a degree that a general influence could at the same time be excluded. The general character of the pulse-curve remains the same even after a more extensive application of heat or cold to the arm. The difficulty in influencing the character of the curve is well illustrated by making tracings with a different amount of pressure upon the spring. Although the height of the curve as a whole, and that of the secondary curves, will be influenced, neither the general shape of the curve nor the number and position of the secondary elevations will be affected in the least. This remains true even if the artery be almost compressed at the periphery, and such a compression would apparently be quite similar to the effect of a sharp vasomotor contraction there. This fact convinced von Frey that the best way to employ the sphygmograph was with a very strong pressure of the spring, thus avoiding any excessive swinging of the registering lever. The more frequently and carefully one employs the sphygmograph, the more one is convinced that it registers the condition of the general, *i. e.*, the aortic, circulation, and that it is but slightly influenced by local vasomotor influences. The sphygmogram is, first of all (and herein lies its clinical value) the expression of the form which the pulse-wave assumes under the circulatory conditions of pressure and resistance in the aorta and its large branches. Another thing worth remembering is this, that excessive vasomotor conditions, such as Mosso employed (local baths, violent muscular motions, etc.), rarely affect the ordinary radial beat. If they did we should notice other evidences of vasomotor action, such as an increased temperature or redness of the skin. The radial vasomotor tonus of an individual ordinarily clothed and reasonably quiet in all probability varies but little from the average value, which depends upon the condition of the general circulation.

One practical difficulty with the sphygmograph is that in one case, even under physiologic conditions, the curve of the individual pulse may present several peculiarities which in another case would signify some pathologic variations. Hence, a sphygmogram is more practically useful in following the circulatory conditions in the same patient, *i. e.*, for what might be termed functional diagnosis of circulatory disturbances, than for ordinary diagnostic purposes. It is of decided assistance in studying more closely the therapeutic action of certain measures upon the circulation and of determining the more rational plan of treatment in a given case. Jaquet's sphygmograph is especially suitable for such comparative investigations, not only because an accurate time-recording apparatus is attached, but also because the amount of pressure upon the spring can be exactly reproduced each time. Another advantage is that the examiner can make at each trial five different curves (corresponding to the five degrees of tension in the spring, and so compare them with five others). This will prevent misjudging rather insignificant local variations of vasomotor tension. The increased pressure on the spring evidently has the same effect on the circulation of the hand as a marked increase of tonus of the radial artery. After a little practice one can take five such tracings very rapidly. There is still quite a difference of opinion whether high or low curves present the more correct picture. While the novice will *a priori* prefer high curves, attracted by the inappropriate construction of sphygmographs which give excessive swinging, see Dudgeon's sphygmograph, p. 120, the expert points out that these high curves are deformed by excessive

swinging and that it is better to choose the pressure giving a curve of moderate height. Since the modern instruments (Jaquet's sphygmograph, Model I, II, and III) do not permit much swinging, the high curves seem rather more suitable, because they show that the sphygmograph was very perfectly applied, and because their results are perhaps better for comparison in different patients as well as in the same patient. It is evident that the excursions of the registering-needle will be the highest when the tension upon the spring either just balances or is but very slightly in excess of the average pressure in the artery. (See p. 117.) On the one hand, this is because the transmission of the systolic increase of pressure to the sphygmograph is least interfered with by the relaxed arterial wall; and, on the other hand, because the next wave will back up considerably, and consequently the rise will be magnified, just as with a hydraulic press. Comparing the various pulse-curves with one another, especially under those well-definable conditions and with a perfect sphygmograph, is really very valuable.

VOLUME OF THE PULSE IN THE SPHYGMOGRAM

According to our definition on p. 118, the volume of the pulse is represented by the height of the primary curve summit above the base of the curve. Other things being equal, it is evident that the volume of the pulse depends upon the amount of blood which is thrown into the artery during systole. If this systolic amount of blood be the same, the volume of the pulse then depends upon the facility with which the arterial wall and the pelotte of the sphygmograph give way to the wave motion of the blood, *i. e.*, on the one hand, upon the passive tension of the artery as determined by the blood-pressure, and, on the other hand, upon the active tension of the muscularis of the artery and upon the tension of the spring of the sphygmograph. The volume of the pulse, *i. e.*, the height of the sphygmographic curve, also depends very decidedly upon the size of the surface of the artery (according to Pascal's law of the hydraulic press). With the same strength of systole of the left heart and the same blood-pressure, the larger the diameter of the radial artery, the higher the spring of the sphygmograph will be raised, and hence the larger the pulse. The frequency of the pulse also influences the height of the sphygmogram. If the pulse be rapid, a part of the descending limb of the curve will be cut off by the following wave. So many factors influence the volume of the pulse in ways which we cannot perfectly determine from the appearance of the curve itself, that the mere volume of the pulse is of very uncertain diagnostic significance. In the following cases, provided the tracings compared are all of a maximum height, the volume of the pulse is of some significance:

1. When the size of the individual beat varies in any one pulse-curve, we may be sure that the larger beat corresponds to a larger expulsion (*i. e.*, is preceded by a more complete diastole of the heart), and that the smaller beat corresponds to a smaller expulsion.

2. If the same patient's pulse become fuller and of lower tension when examined with the same sphygmograph (see pp. 131 and 146 *et seq.*), we are justified in assuming that a greater systolic expulsion is the cause.

On the other hand, if the full pulse be at the same time of increased tension, its increased size can be due only to the fact that with the increased resistance in the circulation and the resulting high blood-

pressure, even a smaller systole produces a marked increase of pressure in the arterial tube, which is already markedly distended and consequently less elastic. The reason for these statements will be found in the section upon Sphygmobolometry.

The following terms refer to the size of the pulse: *Pulsus equalis* and *inequalis* (the latter is usually a *pulsus irregularis* as well); *pulsus inequalis periodicus*. The most interesting types of the latter are the *pulsus alternans* (Fig. 62) and *pulsus paradoxus* (Fig. 64).

Fig. 62.—*Pulsus alternans* (Volhard).

By *pulsus alternans* we understand the alternate occurrence of a large and of a smaller pulse in an almost constant rhythm. The nature of this phenomenon and its differentiation from similar forms of the *pulsus bigeminus* is discussed upon p. 162.

The *pulsus paradoxus*, a poorly chosen name, was first described by Griesinger,¹ and later by Kussmaul, as a constant symptom of indurative mediastinitis. Its peculiarity is that during inspiration the pulse becomes feeble or else cannot be felt at all. Kussmaul explains it as due to an inspiratory pull upon the veins leading to the heart by the

Fig. 63.—An apparent *pulsus alternans*, which was shown, by counting the apex-beats and marking the cardiac sounds, to be actually a pronounced dirotic pulse in which the small, interpolated wave is to be regarded as a dirotic elevation (*pseudotachycardia*, see p. 113).

intrathoracic adhesions. From the explanation given on p. 134 et seq. it follows that this symptom can have no pathognomonic importance in the diagnosis of indurative mediastinitis. From the physiologic significance of the inspiratory diminution in the size of the pulse, as there explained, it is not surprising that it has been observed also in pericarditis, in valvular disease, in weak heart, in pneumonia, in pleurisy, and in stenoses of the air-passages (laryngeal and tracheal stenoses, obliterative bronchitis). Even when the heart and lungs are abso-

¹ Widenmann: *Beitrag zur Diagnose der Mediastinitis*, Tübingen, 1856.

lutely normal, it is possible that respiration may produce some evident effect upon the pulse, although this is not usually the case, as we have previously pointed out on p. 134.

It seems to the author that the *pulsus paradoxus* is of value in the diagnosis of indurative mediastinitis only when there is a concomitant inspiratory engorgement of the jugular veins, a symptom which indicates a stenosis of the jugular veins during inspiration.

The typical *pulsus paradoxus* (Fig. 63) is copied from Kussmaul's original communication. It especially seems to the author to possess no diagnostic importance whatsoever. As is easily seen from the figure, the *pulsus paradoxus* is just twice as frequent as the respirations, so that expiration always coincides with one beat and inspiration with the other. If the breathing be energetic, this relation will naturally emphasize the physiologic factors described on p. 134. As a matter of fact, the breathing is rapid, so that under the circumstances, according to p. 134, with each diminished filling of the arteries, the pulse shows more or less distinctly an inspiratory decrease or even a disappearance. Besides, from what has been mentioned on p. 134, it is evident that under certain circumstances, and practically independent of the frequency of the respiration, a noticeable diminution or even an omission of the pulse may be observed, even during expiration. Such a phenomenon might just

Fig. 64.—*Pulsus paradoxus*: *E, E*, Beginning of expiration; *J, J*, beginning of inspiration (Kussmaul).

as well be called a "*pulsus paradoxus*," and it certainly has just as little significance in the diagnosis of any definite disease.

Although all these phenomena of an alteration in the pulse from respiratory influences coincide with the occurrence of a low arterial pressure (p. 134), we are not justified in diagnosing from their presence any one definite disease, such as pericarditis or mediastinitis, but merely a deficient general peripheral circulation, *i. e.*, an insufficient arterial filling.

CELERITY OF THE PULSE IN THE SPHYGMOGRAM

The celerity of a pulse is a quality which we can appreciate by palpation (p. 115). It is also plainly represented in the sphygmographic curve by the more or less marked abruptness of the ascending and of the descending limbs of the curve, and is measured mathematically by the angle formed by these limbs. Both ascending and descending limbs of a *pulsus celer* are steep and the summit is sharp (Fig. 64). On the contrary, both limbs of a true *pulsus tardus* are sloping, the curve is flat and the summit blunt (Fig. 65). Either limb of the curve may exhibit the signs of celerity or tardiness, while the other limb either is not affected or may exhibit the opposite condition. In this case our description must include the character of each limb. For the method of determining by construction the shape of the general curve, or of the main summit in the case of polycrotic curves, see Fig. 54.

A variety of the pulse of aortic insufficiency is encountered in the older literature as the so-called Corrigan pulse, which, in addition to the general characteristics of celerity, exhibits another peculiarity in that an anacrotic notch is present near the apex of the ascending limb, which is frequently followed by a plateau. Such curves are evidently due, however, to the excessive swinging which was always present in the older sphygmographs.

The usual absence of dicrotism in aortic insufficiency is due not to the defect in the aortic valve, which thus accounted for the absence of the "recoil elevation," in the old erroneous theory of the dicrotic wave, but simply to the pronounced celerity, i. e., to the marked diastolic fall of pressure which reduces the reflected waves to a minimum.

Fig. 65.—Pulsus celer in aortic insufficiency (Riegel)

The ascending limb in aortic insufficiency (Fig. 65) is steep because a large mass of blood is suddenly expelled from the distended left ventricle into the aorta; and the descending limb is also steep because, on account of regurgitation of the blood into the left ventricle, the negative stage of the wave is introduced abnormally rapidly. Conversely, the ascending and descending limbs of aortic stenosis are oblique; it is a typical *pulsus tardus* (Fig. 66). Here the rise as well as the drop of the curve takes place slowly because the systolic impulse is deadened and prolonged at the seat of stenosis. In relaxed vessels (e. g., in fever) the rise as well as the drop is usually quick. (See p. 131.) The dicrotic febrile pulse is therefore usually a *pulsus celer* (Fig. 70). With high

Fig. 66.—Pulsus tardus in aortic stenosis (Strümpell).

arterial tension the descending limb of the curve is usually quite gradual and oblique (p. 132), since the blood flows away slowly on account of the great peripheral resistance. The rise is generally rapid and steep on account of the energetic cardiac action. This is the type of pulse which is usually observed in old people with arteriosclerosis (Fig. 67). Nevertheless a very decided degree of arteriosclerosis (Fig. 68) is generally accompanied by a gradual rise. This is probably due to the simple fact that with high blood-pressure the reflex waves (see p. 132) occur so soon that they coincide with the ascending limb of the curve and change its appearance without forming distinct secondary elevations. The rounding of the apex in Fig. 67 is explained in an analo-

gous manner. (See p. 148.) In nephritis (Fig. 69) the rise is steep and the descent slow, but the pulse differs from that of arteriosclerosis by the great number of secondary elevations.

Although the general shape of the sphygmogram gives some idea of the arterial pressure and the way the blood flows into the arteries, and from them to the periphery, yet neither the descent nor the ascent of the

Fig. 67.—Senile pulse in arteriosclerosis (Kriegel).

curve is absolutely diagnostic. In the first place, the height of the curve influences the slant of the descending limb; and, as a rule, we are unable to interpret the significance of variations in the height (p. 141). Again, the frequency of the pulse decidedly modifies the slant of the descending limb, because if a pulse be rapid, a portion of its descending limb is simply cut off by the following wave, so that the

Fig. 68.—Pulse in advanced arteriosclerosis: Slow ascent and descent of the wave; anacrotism—only 32 beats to the minute (taken with Jaquet's instrument).

height of the curve seems lessened. This naturally influences the form and the abruptness of the descending limb, since the retained portion of the descending limb seems abnormally steep when its concavity is directed upward and abnormally flat when its convexity is directed upward. Even in aortic insufficiency the value of the slant of the des-

Fig. 69.—Pulse in chronic nephritis.

cending limb is rather more for demonstration than for diagnosis. The slant of the ascending limb is almost as variable

In order to exclude the height of the sphygmogram, which we have seen to be dependent upon many incidental influences, from our conception of *pulsus celer* and *pulsus tardus*, we should replace the expression "abruptness" of the limbs of the curve by the duration of the ascent and descent which may be actually measured by the sphygmo-

graph. This measurement is made by dropping a vertical from the apex of the curve to the abscissa, measuring the distances from the beginning of the ascent to the vertical line and from the vertical line to the end of the descent, and expressing these distances in time according to the unit marking. The celerity of the ascent or descent will then be inversely proportional to the periods of time. We must, of course, remember that the time interval of the ascending limb should not be confounded with the duration of the cardiac systole, for systole (p. 130) extends beyond the main elevation.

It should be observed that as a result of the fact that the duration of the ascent of the pulse-curve does not correspond with the duration of the delivery of the blood into the aorta, the demonstration of the characteristic pulse of aortic stenosis is frequently unsuccessful, since the duration of the ascending limb of the curve is shortened by the rapid flowing of the blood toward the periphery. The pulse simply seems small, but does not present the typical characteristics of the *pulsus tardus*. To the best of the author's knowledge, attention has not been previously directed to this evident explanation of the frequent absence of the *pulsus tardus* in aortic stenosis.

In conclusion, the author considers that a much more useful and accurate conception of celerity may be obtained from the use of the absolute sphygmogram (see p. 178) than from the preceding definitions.

TENSION OF THE PULSE IN THE SPHYGMOGRAM (POLYCROTISM; DICROTISM; ANACROTISM)

The secondary elevations of the descending limb (p. 131 et seq.) are most significant in attempting to estimate from the pulse-tracing the tension of the pulse, *i. e.*, the mean blood-pressure. Either elasticity elevations which are pronounced and which arise early in the curve (according to von Frey's and Krehl's conception (p. 133), the early reflex waves, *i. e.*, secondary elevations near the summit) or anacrotic elevations (p. 132) generally indicate a *high* mean blood-pressure. The converse, *i. e.*, the so-called dicrotic wave (p. 130), is usually more pronounced with a *low* mean blood-pressure (p. 131 and Note 2, p. 131). Where none of the secondary elevations, either from its size or its position, can be considered as a dicrotic wave, we are justified in assuming that numerous and pronounced secondary elevations are more in favor of a high pressure; because, according to Landois, these numerous elevations should be regarded as powerful, and, at least in part, early reflex waves.

(See p. 131 et seq. and p. 144 in regard to the general form and size of the pulse under variable mean pressure.)

Although exceptions frequently occur on account of the complicated conditions of wave reflection (see p. 133), the type of the pulse-curve with varying arterial pressure may be represented as follows:

1. *Normal Pressure*.—Both the elasticity elevations and the dicrotic wave are moderately developed; the latter, however, differs very little from the elasticity elevations. (See Fig. 53.)

2. *Low Pressure*.—Elasticity elevations disappear, dicrotism increases, and eventually becomes transformed into monocrotism, *i. e.*, the pulse becomes a *pulsus celer* (Fig. 70, *b, c, d, e*).

3. *High Pressure*.—Elasticity elevations increase in size and number; they are situated nearer the summit (Figs. 69 and 71) or even on the ascending limb of the curve (anacrotic); the descending limb, and in rare cases the ascending limb (see p. 144 et seq.), are oblique (*tardus*).

If the blood-pressure be very high, and especially if it be due to arteriosclerotic resistance, not only the dicrotic rise disappears, but even the elasticity elevations fade away more or less completely, because the arterial wall has become stiffened either on account of the firm contractions of its muscularis or on account of the arteriosclerotic changes. While this is the usual explanation of this phenomenon, it is perhaps more likely that it is due to the reflected waves being transmitted with such velocity that they disappear in the main apex of the curve. A monocrotic pulse finally results. Fig. 68 represents such a slow and almost monocrotic sphygmogram; but there still remain some indica-

a. Normal with beginning dicrotism.

b. Hypodicrotism.

d. Hyperdicrotism.

e. Monocrotism.

Fig. 70.—Increasing dicrotism, finally transformed into monocrotism (Riegel).

tions of elasticity elevations visible especially in the ascending limb (anacrotism).

In this schematic grouping the relation of the celerity of the pulse-curve to the blood-pressure has only a theoretic significance, because the quality of celerity in the sphygmogram (pp. 141 and 145) possesses only slight diagnostic value.

In reference to the practical diagnostic significance of the tension of the pulse as a clinical expression of blood-pressure (see p. 173 et seq.) upon the diagnostic significance of the measurement of the arterial pressure

Furthermore, merely counting the elasticity elevations is not always sufficient to determine the height of the blood-pressure, because the pulse frequency always plays a part. With a frequent pulse the curve is not completely developed, so that a part of the descending limb and the elasticity elevations contained in it will not show.

Under certain conditions pronounced dicrotism may simulate a pulsus bigeminus

or even a *pulsus alternans* (see Fig. 63, p. 142), just as, upon the other hand, an indistinct bigeminus from extrasystoles may simulate dicrotism and constitute pseudo-bradycardia. (See the curve of pseudobradycardia depicted in the section upon The Graphic Registration of the Cardiac Impulse.)

The development of a dicrotic wave is best studied in a febrile pulse, because dicrotism usually goes hand in hand with a diminution of the vascular tension. The higher the fever, the more fully the dicrotic wave is developed, and the further distant is it from the main summit of the curve (Fig. 70, *a, b, c, d*). The individual steps of this change have received separate names. If the dicrotic elevation begins before the descending limb reaches the base of the curve, the pulse is called *hypodicrotic* (Fig. 70, *b*). It is strictly *dicrotic* when the dicrotic wave starts only after the descending limb reaches the base line. If the dicrotic wave occurs still later, *i. e.*, in the ascending limb of the following wave, the pulse is termed *hyperdicrotic* (Fig. 70, *d*). This peculiarity may arise either because the dicrotic wave is retarded or because the following wave, coming so rapidly, cuts off the descending limb of the dicrotic wave. If in Fig. 70, *c*, the ordinary dicrotic pulse, we imagine that the individual beats follow more closely one after the other, "hyperdicrotism" results (Fig. 70, *d*). If the dicrotic wave be still further retarded, or, what amounts to the same thing, if the rate of the pulse be still further increased, a monocrotic wave results (Fig. 70, *e*). This monocrotism with relaxed vessels and low pressure differs from the monocrotism of high pressure (Fig. 68). In the latter either the tense or rigid arterial wall cannot produce any considerable secondary elevations, or the secondary waves are reflected with such velocity that they become lost in the main apex of the curve. The pulse-wave is here usually tardus and the pulse very infrequent, probably because the heart is slowed by irritation of the vagus from high blood-pressure.

Mackenzie (*loc. cit.*) thinks that the old conception of sthenic fever may be best defined by the use of the sphygmogram. He believes that the marked development

Fig. 71 —Tense pulse in lead colic: Some of the waves anacrotic (Riegel).

of dicrotism determines the character of sthenic fever (*i. e.*, favorable), while the slight tendency to dicrotism is equally characteristic of the asthenic or unfavorable fever pulse. He sees in the absence of pronounced dicrotism the sign of a low reserve of pressure during diastole, a low minimum pressure, that is to say, the sign of insufficient cardiac energy or of pronounced vasomotor weakness. Since we have seen, however, that the form of the pulse-curve is influenced by the frequency of the pulse, by the diameter of the artery, and by the application and peculiarities of the sphygmograph in a manner beyond all calculation, Mackenzie's conclusions in this respect cannot always be to the point. They would more likely be correct if they were based upon the absolute (p. 174 et seq.), instead of upon the actual sphygmogram, since we would then be comparing curves of the same frequency and gaining information in reference to the absolute volume of the diastolic fall.

In the absolute sphygmogram the sthenic fever would be characterized by a moderate, the asthenic fever by an excessive, diastolic fall of pressure. Typical examples of high-tension pulse-curves are the arteriosclerotic pulse (Fig. 68), the nephritic pulse (Fig. 69), and the tense pulse in lead colic (Fig. 71).

Anacrotic elevations (p. 132) probably occur only with high blood-pressure. Fig. 71 shows anacrotism in some of the summits, and it is also suggested in the curve of Fig. 68. Rounded summits (Fig. 67) probably signify anacrotism consisting of several anacrotic elevations. The rigidity of the artery prevents it from being distinctly indicated. Similarly, rounded tops which slant off toward the descending limb should probably be imagined as confluent anacrotic elasticity elevations. Sometimes the rounded top is flattened like a plateau, but the significance is probably not changed. Such curves must not be confounded with those of the "negative sphygmogram." (See p. 134.)

SPECIFIC SPHYGMOGRAMS

When the sphygmograph was first employed, it was believed that pathognomonic pulse-curves would be found to characterize certain affections, especially cardiac cases. But such a belief has not been justified. Not even the curve of aortic insufficiency can be considered specific of this disease, for in fever and in exophthalmic goiter, without any leak at the aortic valve, a very pronounced *pulsus celer* is often observed. The pulse-curve of mitral lesions is less suggestive or certain, although in some instances it is of decided assistance in the diagnosis. A serious error was formerly made in the attempt to find characteristic signs in the curve during the time of disturbed compensation. This is evidently the least favorable time, because if compensation be affected to any extent, the pulse will always be small, weak, and of low tension; and such a condition might be due to the valve lesion alone, without any disturbance of compensation. v. Noorden¹ has par-

Fig. 72.—Tense pulse in compensated mitral stenosis (v. Noorden).

ticularly emphasized the necessity of utilizing well-compensated cases in order to obtain characteristic curves, and believes that compensated mitral stenosis exhibits a high-tension pulse, whereas compensated mitral insufficiency exhibits a low-tension pulse (Figs. 72 and 73).

v. Noorden accounts for this phenomenon by assuming that in mitral stenosis an increased arterial tone aids in maintaining the compensation. The arterial system is thus sufficiently filled and the pressure preserved despite the small systole. On the contrary, in mitral insufficiency the compensation is favored by vasomotor relaxation of the vessels, which diminishes the resistance in the arterial system. In this way a much larger proportion of the left ventricular contents can be utilized by the circulation, and a correspondingly smaller portion returns into the left auricle. These peculiarities are, the writer believes, more simply explained

Fig. 73.—Lack of tension of the pulse in compensated mitral insufficiency (v. Noorden).

as follows: In mitral stenosis there is no reason for any diminution of the arterial pressure; whereas in pronounced mitral insufficiency a high arterial pressure cannot possibly occur because of the regurgitation of the blood into the left auricle. An approximately normal circulation in such a marked degree of mitral insufficiency, in spite of the low arterial pressure, is an indication that the vasomotor tone of the general circulation is lowered, a fact which has a compensatory significance, and to this extent v. Noorden is correct.

A FEW PRACTICAL EXAMPLES TO ILLUSTRATE THE APPLICATION OF THE SPHYGMOGRAPH

The deductions which may be made from the sphygmogram as to the condition of the circulation are well illustrated in Fig. 75, *a* and *b*, and Fig. 76, *a* and *b*. They

¹ Charité-Annalen, 15 Jahrgang.

represent tracings taken—(a) from a case of disturbed compensation and (b) from the same case after compensation has been reestablished by the employment of digitalis.

The comparison of curves in Fig. 75, a, and Fig. 77 is very interesting from a diagnostic standpoint. Both curves show an irregular pulse, but with these differences: The curve in Fig. 77 in general, and the small interposed beats, represent a

a

b

Fig. 74.—Sphygmogram from a patient with mitral insufficiency, to demonstrate the action of digitalis: a, Before the administration of digitalis—circulation decidedly affected, radial pulse 128, cardiac beats 172; b, after the employment of digitalis—circulation practically normal.

pulse of high tension, whereas the pointed single elevations of the curve in Fig. 75, a, point in general to a low degree of tension. The arterial pressure sinks quickly, especially in the little beats; this is evident from the dirotism and from the depression of the base of the curve. The latter fact alone points to an insufficient systole as compared with the curve in Fig. 77, where the cardiac apparatus is evidently sufficient.

a

b

Fig. 75.—Sphygmogram from a patient with emphysema and cardiac dilatation, to demonstrate the action of digitalis: a, Before the administration of digitalis—circulation decidedly affected, pulse about 100; b, after 2 gm. of digitalis—circulation normal, pulse 70.

The type of irregularity illustrates another difference between the two curves. In Fig. 75, a, the size of the individual pulse-wave certainly in some places seems to be independent of the size of the preceding interval, whereas in Fig. 77 the size of the individual beat is directly proportional to the duration of the preceding interval. The first type of irregularity, according to the author's experience, always points to cardiac insufficiency, for when the pulse is smaller after a long pause than after

a short one (whether it be a normal systole or an extrasystole), this can be due only to an incomplete systole, and the condition can be helped by employing digitalis. This drug will improve the flow of blood through the cardiac muscle itself, and so help the disturbed innervation which is the cause of the arrhythmia.

Fig. 76.—Pulsus bigeminus from extrasystoles, with compensatory pause, in a case of chronic pericarditis before the intravenous injection of 0.0003 digitalen (Jaquet's sphygmograph, new model). This phenomenon was present for days.

The irregularity represented in Fig. 77 is quite different. Here the difference in volume of the beats is a direct sequence of the irregularity. Because the left

Fig. 77.—The pulse of the same patient, five minutes after the intravenous injection of digitalen. The bigeminus has disappeared. Upon the other hand, however, it is well known that bigeminus not infrequently follows the administration of digitalis.

ventricular diastolic filling is brief, the succeeding pulse must be smaller, even if the cardiac power be entirely sufficient. This type of irregularity, therefore, does

Fig. 78.—Arrhythmic sphygmogram in cardiac sufficiency.

not point to cardiac insufficiency, and so in itself presents no indication for the use of digitalis. The size and the high tension of the individual pulse-wave evident in Fig. 77 would be another reason for the uselessness of digitalis in this case.

THE EMPLOYMENT OF COMPARATIVE SPHYGMOGRAPHY IN THE DIAGNOSIS OF ANEURYSMS AND NARROWINGS OF THE MAIN ARTERIES GIVEN OFF BY THE AORTA

Marey¹ and Francois Franck² have made simultaneous records from vessels proximal and distal to an aortic aneurysm (p. 108), and found that the pulse-wave

¹ *La Circulation du sang*, 1881.

² *Journal d'anatomie et de physiologie*, 1878, vol. xiv.

in the distal vessel was delayed as compared with the pulse-wave in the proximal one. They also found that the delay was manifested both in the beginning of the ascent and, to a still more marked degree, in the apex of the curve. v. Ziemssen¹ and Mackenzie,² however, recognized only the delay in the apex of the curve, but none in the beginning of the ascending limb. Even to-day this question remains undecided, since the examinations have not always been made by methods free from objections. From what has previously been said in general, in reference to *pulsus celer* and *pulsus tardus*, it follows that a retardation of the apex of the curve must not be assumed from the general form of the ordinary sphygmogram (from the steepness of the ascending limb), but only from the absolute sphygmogram, or at least from a comparison of the duration of the ascent. Even a diminution in the size of the pulse-wave may simulate a *pulsus tardus* in the ordinary sphygmogram, just as the palpating finger may recognize both the delayed ascent and the delayed apex. The same statements are true of the retardation of the apex of the wave in an artery which is stenosed at its origin, such as is frequently the case with an artery coming off from an aneurysm by means of a distorted, slit-like opening. It is said that retardation of the apex occurs under these conditions, but such observations must be confirmed by measurement. Upon the other hand, both von Ziemssen and Mackenzie state that the beginning of the ascent occurs no later in a stenosed than in a corresponding normal artery.

Such simultaneous records may be taken by means of the instruments described upon p. 126 et seq. If the simplified Jaquet's sphygmocardiograph (p. 128) be employed, one artery is allowed to trace directly by means of the spring-sphygmograph, while the other traces upon the same strip of paper by means of pneumatic conduction. If we wish to compare two arteries, *e. g.*, the carotids, the curves of which can be comfortably taken only by pneumatic conduction, each carotid is in turn allowed to record itself in this way upon the same strip of paper which receives the direct synchronous tracing of the radial artery of the same side. The time relations of the two carotid curves may then be determined by comparison with the radial curves, which thus serve as a time-abscissa, Mackenzie's polygraph (p. 128) may also be advantageously employed for such records. With the exception of the radial artery, simple glass funnels or small metal beakers, such as those used by Mackenzie in his polygraph, may be utilized as receivers for the pneumatic registration (p. 128). If we wish to compare the two radial pulses and have no appropriate receptive appliance for the radial artery, we may take a direct tracing of each radial in turn, and upon the same strip of paper a synchronous pneumatic record from the carotid. This curve is easily obtained from the carotid without any special receiving appliance by means of a small funnel held by the hand. The carotid curve thus serves as a third factor in the comparison.

It should finally be stated that if it be desired to determine only the relation in time of the apex of the curve to the beginning of the ascent, this may be accomplished by taking two consecutive sphygmograms of the ordinary variety by means of the Jaquet sphygmograph, and then comparing them by means of the time markings.

THE MODERN ANALYSIS OF THE IRREGULAR PULSE

Introductory Note.—This chapter will consider chiefly the disturbances of the regularity of the pulse sequence as observed in the peripheral arteries, *i. e.*, pulse arrhythmia in the restricted sense of the word. It will also treat of the anomalies which sometimes occur, either with or without these arrhythmias, and which depend upon disturbances of the harmonic and physiologic coördination of the individual portions of the heart. It will finally take up the disturbances of the strength or volume of the arterial pulse as they occur from beat to beat, *i. e.*, the disturbances of the consecutive contractions of the heart, since all these disturbances have many points in common.

To understand what follows, we must take for granted Engelmann's supposition that the physiologic rhythmic stimulation for cardiac activity proceeds from the opening of the great veins into the heart to the auricle and the ventricle. The normal heart action is the physiologic response of the heart muscle to these physiologic rhythmic stimulations. In addition we must accept as proved (again according to Engelmann's experiments) that there must be differentiated as special properties of the heart-muscle fibers a power to produce stimulation, an irritability or stimulability, a power of conducting stimulation, and a capacity for contraction. These

¹ Arch. f. klin. Med., 1890, vol. xlv.

² The Study of the Pulse, 1902.

peculiarities, Engelmann maintains, are inherent in the muscle-fibers themselves, but may be altered positively or negatively by many influences, which proceed partly from the nervous system. Engelmann differentiates *positive* or *negative chronotropic* influences, by which the number of the physiologic automatic stimulations is increased or diminished in the unit of time: *positive* or *negative bathmotropic* influences, which increase or diminish the irritability or stimulability; *positive* or *negative dromotropic* influences, which increase or diminish the conduction power of the heart-muscle fibers; and, finally, *positive and negative inotropic* influences, which affect the contracting power of the heart-muscle fibers.

Many regard the so-called "myogenic theory" of the cardiac activity as an integral portion of this teaching, according to which the cardinal characteristics described by Engelmann are peculiar to the muscular fibers themselves without the intervention of the neurocardium. This, however, does not seem justifiable, since these characteristics could still exist even if it were finally shown that all of them except contractility, which is, of course, a property of muscular tissue, are located in the neurocardium. The question is rather whether these characteristics are to be so sharply differentiated from one another as independent qualities, or whether they increase and diminish in harmony, and are consequently to be regarded as the expression of the general irritability of the myocardium or neurocardium.

In a great number of cases an exact analysis of the irregular pulse is possible only when all our methods of diagnosis are employed. The most important of these methods is sphygmography, which records the pulse in series of some length, and makes it accessible to exact measurement according to time and dimensions. For this purpose, the only sphygmographs to be employed are those, like Jaquet's or Dudgeon's, which record a long series of waves. The measurements are made along the abscissa, which furnish conclusions in reference to rhythm and of the height of the curve, which in this case gives us an accurate basis for comparing the volume and strength of the individual waves, because it refers to the same tracing. For the interpretation of the phenomena of the irregular pulse, however, we must also study the action of the heart as well as the pulsations of the radial artery. This may be done by palpation of the cardiac impulse, by auscultation, by inspection of the venous pulse, and, still more accurately, by a graphic record of the cardiac impulse taken synchronously with the arterial or with the venous pulse. Recently the synchronous sphygmographic records of the radial and of the venous pulse have furnished the most important and otherwise unobtainable conclusions as to the character of certain arrhythmias, since the venous pulse gives information in reference to the action of the right auricle and sometimes also to that of the right ventricle. The study of the venous pulse is consequently a prerequisite for the proper understanding of the following (p. 192 et seq.). A marked advance has been made by the instruments described on p. 120 et seq., particularly by the simplified Jaquet sphygmocardiograph and Mackenzie's polygraph, by means of which any practitioner may obtain the necessary simultaneous records of the various phenomena. Although but two different records may be made simultaneously with either of the above-mentioned instruments, we may take consecutively the carotid pulse and the radial pulse, the radial pulse and the cardiogram, and the radial pulse and the venous pulse, and then determine the relative times of all these phenomena, as is done by Mackenzie, by comparing them with the radial pulse, which thus serves as a basis of comparison. The following exposition of the analysis of the irregular pulse is consequently based upon a knowledge of the mutual relations of all these phenomena in reference to time. The credit for laying the foundation of the modern clinical analysis of pulse arrhythmias is due particularly to Wenkebach¹ and Mackenzie.²

For the proper understanding of what is to follow it is also necessary to have a clear conception of ineffectual systoles and of extrasystoles. By ineffectual (futile) systoles³ we understand those which are not complete enough to produce a pulse-wave in the radial artery, and which may be recognized only by auscultation of the heart or by palpation or graphic records of the apex-beat. In such a case either only the first or two heart tones are audible to auscultation. The cause of the

¹ Zeit. f. klin. Med., 1899, vol. xxxvi; 1899, vol. xxxvii; and 1900, vol. xxxix; also the monograph, Die Arrhythmie als Ausdruck bestimmter Functions-störungen des Herzens, Leipzig, 1903.

² The Study of the Pulse, 1902.

³ Quincke and Hochhaus, Deut. Arch. f. klin. Med., 1894, vol. liii, p. 414; see also the section upon ineffectual (futile) heart contractions in the chapter, "Cardiac Impulse."

futility may be either that the particular systole is so premature that the ventricle has not had time to fill sufficiently, or that the contraction is not strong enough to produce a perceptible pulse-wave in the peripheral artery. By an *extrasystole*, however, we mean simply a premature systole, and it matters not whether the peripheral pulse is of approximately normal volume or whether, as is usually the case, the pulse-wave is more or less diminished in size or even entirely absent (futile extrasystole). From this it follows that a futile systole is not necessarily an extrasystole, although such is usually the case, and that, upon the other hand, an extrasystole may be futile, but is not so of necessity. This terminologic consideration is of still greater necessity for the proper understanding of what is to follow, since a certain confusion upon this point exists in the literature. The cause of the dwarfing of the pulse-wave of extrasystole is a double one. It is usually due to the fact that the systole is so premature that the ventricle has not become sufficiently filled during the diastole to make possible a normal beat. In addition to this, however, an extrasystole may produce a diminished pulse-wave, because the heart has not had sufficient time to recover itself and consequently suffers in its contractility. Extrasystoles may occur singly in a pulse-tracing or in series of varying length. Single interpolated extrasystoles, if at all recognizable in the arterial pulse, manifest themselves as the *pulsus bigeminus* (Fig. 60, p. 138), i. e., they form together with the preceding normal pulse a twin group which is separated from the following pulse by a longer pause, i. e., by a longer depression of the pulse-wave. This pause may vary. It may be of the same duration as that of the normal pause, and in this case we speak of a shortened bigeminus, since the period of the *pulsus bigeminus*, taken as a whole (counting together the two pulses making up the bigeminus), is of shorter duration than the sum of two normal pulses. (See Fig. 79 from Mackenzie.)

Venous
pulse

Radial
pulse

Fig. 79.—Shortened bigeminus. Auricular extrasystole, according to Mackenzie (*loc. cit.*, Fig. 266, p. 263), with shortened bigeminus. The extrasystole in the radial corresponds to a premature auricular wave *aa*. *a*, Auricular wave; *v*, so-called ventricular wave. (See p. 196.)

Upon the other hand, the pause following the extrasystole may be longer than a normal one—so long, in fact, that the following pulse occurs at just the same place it would have done had there been a normal instead of an extrasystole (Figs. 81 and 82). This lengthened pause is usually designated as a compensatory pause, since it compensates for the early extrasystole. In this case we speak of an unshortened bigeminus, since the duration of two systoles as a whole is not influenced by the premature systole. Between these two types of extrasystole there are transition forms which may be designated as instances of an incomplete compensatory pause or of an incompletely shortened bigeminus. The causes of these variations will be discussed with the different types of arrhythmia. It should also be noted that entire series of extrasystoles may be interpolated in the regular pulse sequence, so that we get a *pulsus trigeminus*, a *pulsus quadrigeminus*, or, when the number is still greater, what is known in general as a series of extrasystoles. In these cases the last extrasystole is separated from the following normal systole by either a normal or a compensatory (lengthened) pause.

A. Arrhythmias from Contractions Arising at an Abnormal Time (Arrhythmias from Extrasystoles)

(a) Cases in which the auricles and ventricles both take part in the irregularity dependent upon premature contraction, and in which the interval between the auricular and the ventricular contractions is consequently unchanged. Auricular extrasystoles.

If a physiologic venous pulse be demonstrable, its rhythm coincides with that of the ventricle.

¹ The direct examination of the venous pulse gives us our knowledge in reference to the right auricle, and the contractions of the left ventricle may be studied in a similar manner.

In this class of arrhythmias Mackenzie differentiates those cases in which the pulse interval simply varies in an irregular manner about a certain average, and those in which a single premature contraction of the auricle and ventricle or a series of such contractions is interpolated in the regular pulse sequence. Mackenzie has observed instances of the first group, chiefly at the beginning of puberty, in individuals who are otherwise normal, and consequently designates them as infantile arrhythmias, or as the infantile type of arrhythmia. This type has also been observed by him in postfebrile bradycardia and during convalescence from cardiac disturbances in the adult. Although the accurate diagnosis of this type of arrhythmia must be based upon the persistence of the normal relationship between the venous and arterial pulses, the diagnosis is probably correct when the intervals vary irregularly, provided no pauses occur which correspond to double the normal pulse period, thus indicating futile extrasystoles absent in the radial, and, further, provided auscultation of the heart also reveals no futile systoles.

It must be admitted that the type designated by Mackenzie as infantile cannot be sharply differentiated from the other arrhythmias of this class (in which both auricle and ventricle exhibit arrhythmia in the same manner). It also seems more or less optional whether or not we should designate those systoles of the infantile arrhythmia which are preceded by shorter pauses as less premature extrasystoles, especially because here also they regularly seem somewhat diminished, as is the case with all extrasystoles. There is perhaps rather a graded difference between them and cases of this same group, in which the systoles are so premature that they induce an omission of the pulse or else produce markedly deformed pulse-curves at the radial artery, which are unmistakable extrasystoles.

An example of this latter type is seen in Fig. 79 from Mackenzie.

Since the right auricle takes part in all these cases in the same manner, we can characterize this group "Aa" as auricular extrasystoles, i. e., extrasystoles which

Venous
pulse

Radial
pulse

Fig. 80.—The infantile type of arrhythmia, according to Mackenzie (*loc. cit.*, Fig. 262, p. 261). The auricular venous pulse takes part in the disturbance. The lengthened pause gives no evidence of a contraction of any kind. a, Auricular wave; v, the so-called ventricular wave (p. 196), c, the carotid peak (p. 197).

originate in the auricle, from which the contraction is transmitted to the ventricle in the usual manner. A characteristic of this form of extrasystole is that the subsequent diastole is not necessarily materially lengthened. This is evidently due to the fact that in these cases the extrasystole acts exactly like a normal systole, so that after a diastole of normal duration the conditions producing the contraction repeat themselves. Such an instance is depicted in Fig. 79, where the sum of the duration of the preceding pulse and of the premature pulse is shorter than the duration of two normal pulses, and a so-called shortened bigeminy is produced. This condition is in contrast to the cases about to be described (see Ab), in which the extrasystoles proceed from the ventricle. It must, nevertheless, be noted that even with auricular extrasystoles, provided they are very large and not markedly premature, the diastole of the extrasystole may be longer than the normal diastole, and that a "compensatory pause" may consequently be present. As a result, the sum of the duration of the normal and of the premature pulses may equal the duration of two regular pulses (unshortened bigeminy), as is the case with ventricular extrasystoles (see below). This is an indication that the contraction stimulus following the extrasystole does not occur until the moment when it would have occurred without the extrasystole. Such an example is furnished in Fig. 81. Between these two types of auricular extrasystoles there are also transition forms, since sometimes the diastole of the extrasystole seems longer than normal, and yet not so long that the subsequent pulse and the extrasystole together are of longer duration than two regular pulses (incomplete compensatory pause). These differences possibly depend upon variable locations of the extra stimulus in the auricle. We might assume that when the extra stimulus is located at the site of the physiologic stimulus, the interval following the extrasystole equals the normal interval, because after this period of time the

normal amount of stimulus has collected; but when the extra stimulus is located in some other portion of the auricle, the site of the physiologic stimulus is rendered incapable of producing a stimulus for a longer or shorter period of time on account of the extra discharge which is conducted back there from the abnormal site. For the activity of the stimulus, as is well known, destroys the quantity of the stimulus.

Unshortened bigeminus

Carotid
pulse

Venous
pulse

Fig. 81.—Auricular extrasystoles: *a'*, Premature auricular contraction; *v'*, premature ventricular contraction; *c*, premature carotid wave. The entire duration of the radial bigeminus corresponds to the duration of two regular beats. This is in contrast to Fig. 79, *a*, auricular wave; *a'*, auricular extra wave; *c*, carotid peak (p. 197); *c'*, carotid extra peak; and *v'*, so-called ventricular waves (according to Mackenzie, *loc. cit.*, Fig. 286, p. 275) (p. 106).

From what has been said upon the subject it follows that auricular extrasystoles may be diagnosed from the artery only when the pause of the extrasystole is of normal length. When the pause of the extrasystole is lengthened, a simultaneous graphic record of the venous pulse is the only means by which we can determine whether the extrasystole is auricular or ventricular. It should be further noted that both auricular and ventricular extrasystoles may repeat themselves any number of times.

Venous
pulse

Radial
pulse

Fig. 82.—Ventricular extrasystole. The venous pulse proceeds regularly, while the radial pulse exhibits a premature beat (*s'*) (according to Mackenzie, *loc. cit.*, Fig. 276, p. 270) (designations as in Fig. 81).

Under these circumstances, the characteristic features of the pause can be recognized only in the last extrasystole.

(b) *Cases in which the ventricle¹ alone takes part in the irregularity (ventricular extrasystoles, the pulsus intermittens).*

Ventricular extrasystoles are observed in the most diverse cardiac affections, and sometimes even in apparently healthy individuals. This very frequent occur-

Radial
pulse

Venous
pulse

Fig. 83 —Futile extrasystole with a regular venous pulse. Ventricular bigeminus, unshortened bigeminus (according to Mackenzie, *loc. cit.*, Fig. 275, p. 269) (designations as in Fig. 81).

rence is illustrated in Fig. 82, the venous curve showing that the right auricle beats in a perfectly regular sequence, while in the radial curve a systole, *s'*, is somewhat premature and consequently dwarfed. (See p. 154.)

From measurements of the intervals of the radial curve it will be seen that the bigeminus produced by the extrasystole, *s'*, has exactly the same duration as two

¹ The left ventricle alone is accessible to examination.

normal pulses. The bigeminus is consequently unshortened, since the premature systole is equalized by a compensatory pause. In Fig. 83 a similar condition obtains, but with the difference that the extrasystole, which in this case was demonstrable only by auscultation of the heart or by a graphic record of the apex, does not appear at all in the radial curve, or rather is represented by an intermission of the pulse, while the auricular venous pulse proceeds in a perfectly regular manner. The regular series of the auricular venous pulses shows that the extrasystoles in this case must be ventricular. The reason why a compensatory pause is present is as follows: In a ventricular extrasystole the following normal contraction stimulus, which manifests itself in a contraction of the auricle at the normal time, reaches the ventricle at a moment when the ventricle has been left by the extrasystole in a so-called refractory phase, i. e., incapable of contraction. A pulse is consequently not produced in the artery until the following normal ventricular systole. We have also just learned that the auricle may act in a similar manner in auricular extrasystole, probably when the extra stimulus acts upon some site other than that of the physiologic site for the origin of the stimulus. It consequently follows that the diagnosis of the ventricular origin of the extrasystole can be made certain only by the simultaneous record of the venous pulse. It should also be noted that the subsequent physiologic stimulus coming from the auricle may reach the ventricle when it is no longer in the refractory phase. In this case the extrasystole appears in the sphygmogram as an interpolated supernumerary pulse (*pulsus intercidens*, see p. 138), which falls between two pulses without increasing the interval between them.

B. Irregularities of Cardiac Action from Disturbance of Conductivity in the Heart

(a) *Arrhythmias from regular intermissions as a result of diminished conductivity within the heart. Pulse groups and ventricular bradycardias from disturbed conductivity. Partial or periodic heart-block.*

Fig. 84 represents a type of irregularity of the pulse which is characterized by regular intermissions occurring after a definite number of pulses. Wenkebach regards such occurrences as the result of a diminution of conductivity in the heart. To understand Wenkebach's explanation a few words are necessary. Engelmann

Fig. 84.—Regular intermitting pulse with groups of four pulses (after Wenkebach).

represented the amount of the conduction power within a certain section of the heart as Δ . The conduction power in the venous sinus is represented as Δs , that in the auricle as Δa , and that in the ventricle as Δv . $\Delta a v$ would then represent the power of conduction between the auricle and ventricle, etc. The time in which the contraction stimulus travels from one place to another depends upon the conduction power. The interval $A s - V s$ (between the systole of the auricle and that of the ventricle) is of especial interest. During systole, not only the stimulability, but also the power of conduction Δ is diminished and this forms the basis of the so-called refractory phase. During the diastole both the stimulability and the power of conduction are gradually recuperated. With this explanation it is comprehensible that if the power of conduction, e. g., at the boundary between the auricle and ventricle, be injured it may, after several heart-beats, become so much depressed that finally the stimulus no longer reaches the ventricular musculature in sufficient force to produce a contraction; but that after such a rest, in a certain way forced upon the ventricle, new beats will reappear. Given a certain degree of conduction weakness, this process may be repeated in such a way that one ventricular contraction will regularly be lost after a certain number of heart-beats, and so groups of regular pulses will be interrupted by an intermission. Such groups have for a long time been recognized in physiologic experiments, and called Lucian's periods. If we examine the sphygmogram in patients with such a regularly intermitting pulse more exactly, we find that the intervals between the pulse-beats within a group vary quite decidedly from each other; and that in each group this variation is repeated in a perfectly typical fashion. (See Fig. 84.) From a more accurate analysis of these variations in the intervals of the pulse within a group,

Wenkebach now shows that the regular loss of the pulse (which we are discussing) depends upon a negative dromotropic influence (see p. 153), i. e., upon a disturbance of the conduction power. After the establishment of the pulse the first interval within a group is the largest, and the following intervals are decidedly smaller; but for the most part they again increase somewhat in size, up to a new intermission. This is explained by assuming from what follows (and, moreover, it has been experimentally proved by Engelmann) that the conduction power Δ is injured most by the first contraction after a pause, and is less markedly affected by the following contractions. The annexed diagram (Fig. 85), copied from Wenkebach, illustrates the relations very clearly.

The diagram is based upon the above assumption: that Δ is diminished by cardiac activity itself (by fatigue). The horizontal lines in the figure are to be considered as time abscissæ. The rhythmic physiologic stimulations which arise at the venous orifice are marked at regular intervals upon the time abscissa φ , 20 units apart. The uninterrupted lines drawn obliquely downward to the right are the graphic representations of the course of the stimulation from the venous orifices to the auricle and ventricle. The part of the figure included in the brace A represents the area of the auricle, that included within the brace V the area of the ventricle. The points of intersection of the oblique and horizontal lines represent the moments of time at which the physiologic stimulation, passing from the root of the heart to its apex, first, crosses the auricular border; second, stimulates the ventricular contraction. Wenkebach's own words furnish the best explanation of the rest of the diagram: "The rate of the stimulus contraction at the heart root

Fig. 85.—Diagram to represent a regularly intermittent pulse, caused by disturbance of the conductivity of the heart muscle—one pulse is lost after every four (after Wenkebach).

$T\varphi = 20$; and the interval φ to Vs , that is the time between the stimulus φ and the ventricular systole Vs , in a favorable case (after a pause) = 5; but in an extreme case, where the stimulus is still transmitted just vigorously enough to produce a ventricular contraction = 10. During the contractions the interval φ to Vs is prolonged from 5 to 10. Following the experiment, we may assume that after the first systole of the group φ to Vs is increased 3; after the following systoles, φ to Vs is increased 1 each time.

"Should Δ in each contraction remain equal, as is normally the case, the tempo of the ventricular systole TVs would always equal φ , even if Δ be very slight. A diminution of Δ would occasion the proportionate increase of TVs . But since each systole has another influence upon Δ , the case will be quite different; and in the instance given here, the first interval (represented in the figure) of ventricular systole, $T_1Vs = 23$, being increased by 3, on account of the increase of the interval φ to Vs from 5 to 8. The following intervals of the ventricular systole, T_2Vs and $T_3Vs = 21$, on account of a further increase by 1. Then, however, the limit is reached, and the fifth stimulation is either not transmitted at all or is no longer sufficiently transmitted. The ventricular contraction fails, and an intermission results. The interval φ to Vs in this pause returns to 5, and the duration of the intermission (T_{int}) amounts to 5 less than the double of $T\varphi$; that is, $T_{int} = 2T\varphi - 5 = 35$. The same process is repeated after the intermission. The tempo of the ventricular contraction then depends entirely upon the rapidity of diminution of Δ in regular rhythm of the contraction stimulation, and with it the increase of φ to Vs ."¹

¹ Zeit f klin Med., vol. xxxvii, p. 482.

Wenkebach found that the time relations in the accompanying sphygmogram (Fig. 84) were in complete conformity with this diagram (Fig. 85), and with the explanation given for the intermission. We observe in Fig. 84 that the numbers representing the intervals confirm the view that the periods after the intervals are the longest, the following much shorter, and those still later somewhat longer again. Although it cannot be recognized in the figure, a gradual diminution in the power of conduction occurs toward the end of a group in the pulse-curve, observed as a diminished celerity in the ascending limb of the pulse-wave.

Wenkebach considers that the exact measuring of the pulse-curve shows the size of the interval of the automatic stimulus at the venous orifices T_p , as well as the amount of the diminution of conduction power in the course of a group. The original article should be consulted in this connection.

Gaskell and Engelmann have called attention to the practical point that vagus irritation diminishes the size of Δ . In this way they explain the grouping frequently occurring after vagus stimulation, as well as the appearance of regular intermissions (especially the bigeminal and trigeminal pulse) after employing digitalis, as this drug stimulates the vagus. At the same time if there be a regularly intermittent pulse, digitalis increases the disturbance of rhythm, because it diminishes Δ by vagus stimulation. This also explains how atropin improves certain regular intermissions, as this poison depresses the vagus tonus, and thereby improves the conduction power of the heart muscle.

Still other anomalies of rhythm may arise from more pronounced diminution of Δ . These are all characterized by a certain amount of regularity or even by perfectly regular repetition of the intermissions, i. e., some grouping of the pulses. However, if a longer pulse-curve be taken, the regularity of the grouping need not be absolutely even, because during the observation varied influences may affect the ordinary

by two longer

regular pulse rhythm and the regular pulse with half-frequency (bradycardia) depending upon the amount of injury to the conduction power, i. e., the negative dromotropic influence. Such transitional forms are composed of groups of 6 to 2 pulse strokes. The regular intermitting pulse in groups of 2 strokes is nothing but a special form of the pulsus bigeminus.¹ The real pulsus alternans (p. 162) does not belong here; but according to Wenkebach, to a disturbance, not of the rhythm, but of contractility. In another group of cases the diminished power of conduction is expressed by the appearance, after the intermission, of a single systole, then another intermission, and then a group of several pulse-beats. This Wenkebach has called the "regularly double intermitting pulse," a term, however, which might lead to misunderstanding. Figs. 86 and 88 illustrate and explain the type. Still another serious disturbance of Δ will produce regular group formations, in which the groups are separated by 3, 4, 5, or n cardiac revolutions prolonged through the loss of a systole. Finally, if $n = \infty$, regular bradycardia with half-frequency occurs, as then only the second stimulation is permanently active. (See Fig. 88, y , according to Mackenzie.)

In all the cases thus far described the diminution in conduction power goes only so far as to occasion the loss of a systole more or less often, but we may conceive of a case in which two or even several systoles, one immediately after the other, are lost; then longer pauses (i. e., still more pronounced bradycardia) would result.

In such bradycardias the frequency of the venous pulse may be a multiple of

¹ Wenkebach is justified in calling attention to the fact that the terms pulsus bigeminus and trigeminus had better be discarded, since he shows in his particularly instructive book (p. 171) that sphygmograms requiring these designations are brought about in a number of different ways—by extrasystoles, by disturbed conductive power, and by true arrhythmias—and that, consequently, they should not be classed under one common name.

that of the radial pulse, and if the development of the phenomena be followed clinically it will be noted that the original frequency of the arterial pulse will be reduced suddenly or by groups of $\frac{1}{2}$, $\frac{1}{3}$, or $\frac{1}{4}$, etc. (See Fig. 88, *x*, according to Mackenzie.)

Since Wenkebach has not recorded the venous pulse in his published cases he has failed to furnish accurate proof that the grouping and bradycardia in his cases had been produced according to his supposition. It has been justly pointed out that such pulse groups and bradycardias may be brought about by auricular or ventricular extrasystoles, which repeat themselves in definite sequence and lead to intermissions of the radial pulse. Upon the other hand, Wenkebach's conception of certain types of bradycardia, in which the groups consist of but a single pulse, has been confirmed by Mackenzie by means of simultaneous records of the venous

Fig. 87.—Diagram to explain Fig. 86 (after Wenkebach).

pulse (Fig. 88). Following the precedent of Gaskell and His, Jr.,¹ these cases are usually designated as heart-block, since the conduction of the stimulus from the auricle to the ventricle is blocked or interrupted for one or more systoles. In these cases, however, it would seem desirable to speak only of incomplete or periodic heart-block, because the blocking does not take place with every radial pulse, and because in the following section we will consider cases where the auricles and ventricles beat absolutely independently of one another. We should consequently reserve the expression heart-block, or, still better, complete heart-block, for this latter group. From the preceding observations the "ventricular" bradycardia associated with incomplete heart-block seems to be the usual cause of the slowing of the pulse in the so-called Stokes-Adams syndrome. The cause of the phenomenon, which consists in a disturbance of one of the fundamental qualities of the heart,

Fig. 88.—Bradycardia from the absence of ventricular pulses as a result of disturbed conduction. At *x*, two ventricular contractions are missing, at *y* one, while the continued presence of the regular stimulus is manifested in the curve of the venous pulse. A carotid peak (see p. 195) in the venous pulse is found only when there is a radial pulse (according to Mackenzie, *loc. cit.*, Fig. 292, p. 280).

explains the usually unfavorable prognosis of such a ventricular bradycardia. Other causes however, may probably be responsible for the Stokes-Adams syndrome. It might be, as in Fig. 89, for example, where there is no connection whatever between the ventricular activity and the auricular contractions, and the ventricle beats automatically in a regular and slowed rhythm, each contraction being, as it were, a ventricular extrasystole.

(b) *Complete dissociation of the ventricular rhythm from the rhythm of the auricles due to complete interruption of conduction. Complete heart-block with ventricular automatism. Horizontal dissociation of the heart.*

This occurrence is illustrated by Fig. 89, taken from Mackenzie. It is clear that these cases also can be recognized with certainty only by simultaneous records

¹ Deut. Arch. f. klin. Med., 1899, vol. lxiv, S. 316.

of the venous pulse. The nature of this complete heart-block is likewise doubtful. In the absence of a "ventricular wave" in the venous pulse (p. 197) Mackenzie sees the proof that in these cases also the right ventricle beats independently of the auricle. From the enlargement of the auricular wave of the venous pulse at the

Fig. 89.—Complete dissociation of the ventricular rhythm from the rhythm of the auricles. Heart-block with automatism of the ventricles (according to Mackenzie, *loc. cit.*, Fig. 294, p. 282).

moment of its coincidence with a radial pulse he also concludes that the ventricles act synchronously—that there is simply a so-called horizontal dissociation of the auricles, upon the one hand, from the ventricles, upon the other.

C. Cases with Paralysis of the Auricles and Automatism of the Ventricles

These cases are particularly likely to occur in mitral lesions from the marked overdilatation of the auricles. They are to be recognized by the complete absence of the auricular venous pulse, which is replaced by a ventricular venous pulse, either with or without tricuspid insufficiency (See p. 197.) According to Mackenzie, the ventricular contractions appearing in the radial pulse are quite irregular in their character. Numerous extrasystoles are present in the radial pulse, which, from the nature of things, are frequently not followed by compensatory pauses, since the ventricular beat following the extrasystole is of autochthonous origin, or, in other words, all the ventricular contractions are extrasystoles. One series of extrasystoles may be recognized in the radial pulse, while the other series are futile and are apparent only from auscultation or from a record of the cardiac impulse. Futile extrasystoles in regular sequence may produce an apparent bradycardia in the radial pulse, the nature of which is revealed only by auscultation or by a cardiographic record.

Fig. 90.—Ventricular venous pulse as a result of paralysis of the auricle. (See p. 197.) Complete coincidence of the venous and radial pulses. The rudimentary radial pulses correspond to venous pulses, since even a weak ventricular contraction has an obstructive effect upon the venous current (according to Mackenzie, *loc. cit.*, Fig. 296, p. 286).

Fig. 90 illustrates a complete auricular paralysis in which only ventricular pulses are present (see p. 197) with an arrhythmic radial pulse. From the coincidence of the ventricular venous pulses with the arterial pulses it is evident that both ventricles are working synchronously.

Mackenzie has demonstrated that at least certain forms of paroxysmal tachycardia are due to such instances of ventricular extrasystoles with paralyzed auricles, at least with a paralyzed right auricle, and he supposes that the paralysis of the auricles is not the cause of the entire disturbance, but that it is rather the consequence of an overdilatation of the auricles resulting from the tachycardia.

D. Hemisystole (Vertical Dissociation of the Heart)¹

By hemisystole is understood a peculiar type of cardiac activity in which one-half of the heart contracts more frequently than the other, or in which the ventricles contract independently of each other. The phenomenon might consequently be

¹ See also the section upon the Cardiac Impulse.

designated as a vertical dissociation of the cardiac activity. The diagnosis of hemisystole was formerly considered justified as soon as there were two venous pulses to one radial pulse, since the double venous pulsation was regarded as an indication that the right heart contracted twice as frequently as the left.

Since in partial and total heart-block we have become acquainted with examples of horizontal dissociation of the cardiac action in which the right auricle beats twice as often as the ventricles, it follows that the only justifiable conclusion to be drawn from such a doubling of the venous pulse is that the right auricle beats twice as frequently as the left ventricle. At all events, the occurrence of a hemisystole or a vertical dissociation of the cardiac action is quite a rare phenomenon. Such a possibility is not to be entirely excluded, however, since it has occurred repeatedly in animal experimentation, although usually not until just before death. Mackenzie gives two examples, which he is inclined to regard as instances of hemisystole; however, only one of his cases impresses the author as being possibly of this character, there being three ventricular venous pulses to two cardiac impulses (Mackenzie, *loc. cit.*, p. 277). A further objection which is still possible is that with the diminished contractibility, the contractions of the right ventricle can produce a ventricular pulse on account of the low intravenous pressure, while the corresponding radial pulse and even the apex-beat may be absent as a result of the cardiac weakness.

E. Disturbances of the Rhythm from Disturbances of the Contractility; Inotropic Arrhythmias; the Pulsus Alternans

The ventricular contraction may fail if the contractility of the heart muscle has been affected, even though the stimulus rhythm remains normal and the conduction power good. The resulting arrhythmia will be appreciable, both to palpation of the pulse and in the sphygmogram. In this case it depends merely upon negative inotropic influences. (See p. 153.) A grouping of more or less distinct regularity may occur from the summation of fatigue phenomena. The palpating fingers may obtain the impression of an arrhythmia even from a decided diminution of certain systoles. These arrhythmias, which the author would describe as "inotropic arrhythmias," can generally be diagnosed by the differences in the size of the pulses, although without any marked crowding of the periods. The pulses which fail, and to which no extrasystoles correspond, are, of course, excepted.

Pulsus alternans must be discussed here among the inotropic arrhythmias because it does not belong to the true arrhythmias and because it arises from a disturbance of contractility. A more careful examination and measurement of its pulse-curve shows that it presents a very characteristic though insignificant deviation of rhythm from the normal. It comprises a pulse series with large and small pulse-waves alternating regularly with one another at almost equal intervals. (See Fig. 62, p. 142.) Wenkebach¹ has analyzed this pulse most accurately, and decided that it depends upon a disturbance of the contractility for the following reasons: It certainly cannot depend upon a variation in the intensity of the contraction stimulus, because, as is well known, the heart always reacts maximally, even to a diminished stimulus, provided that the latter is sufficient to cause any contraction at all. For the same reason it cannot be due to a diminished power of conduction. It is incorrect to suppose that it could depend upon an extrasystole occurring practically half-way between two normal systoles; because, in the first place, it is quite exceptional for extrasystoles to persist regularly for so long a time, and especially because extrasystoles interposed almost in the place of the normal systoles would produce practically a normal pulse. Wenkebach's explanation is better. He considers that it depends upon a disturbance in the contractile power. After the stronger contraction, the contractile power is not sufficiently recuperated to respond with an equally vigorous systole to the next stimulus. After the weaker contraction, on the contrary, the heart muscle recuperates completely and the succeeding contraction is again more efficient. Regulated in this automatic fashion the pulsus alternans continues until the contraction ability becomes normal again. In conformity with the view that his cases of pulsus alternans depended upon a pure diminution of the contractility, Wenkebach adduces the earlier appearance (anticipation) of the smaller pulse, i. e., the interval between greater and smaller pulse is shorter than that between smaller and greater pulse. In explanation he assumes that the stronger and weaker contractions differ not only in their strength, but also in the rapidity of their occurrence. B. F. Hoffmann,² in fact, did demonstrate that the contractions of the heart muscles

¹ Zeit. f. klin. Med., 1902, vol. xlv, parts 3, 4, p. 218.

² Pflüger's Archiv, 1901, vol. lxxxiv.

occur more rapidly in a hypodynamic condition (*i. e.*, with less contractile power) than with normal contractility. If we assume that the smaller beats of the *pulsus alternans* occur more rapidly than the larger, it follows that the beginning of the smaller pulse will anticipate in the radial curve, as contrasted with the beginning of the greater pulse, because it is more rapidly transmitted to the peripheral arteries.

Volhard has shown, however, that a pulse-curve possessing the characteristic described by Wenkebach, viz., the smaller arterial pulse anticipates, should not be called a true *alternans*, but rather a *pseudoalternans*. That is to say, it is not to be regarded as the result of a pure disturbance of contractility, but as a disturbance of rhythm from bigemina or from extrasystoles, and that the true *alternans*, on the contrary, is characterized by the fact that the smaller pulse in the artery is somewhat delayed. For a more minute description of this conception the reader is referred to Volhard's discussion in the *Münch. med. Wochenschrift*, 1905, No. 13, and only the important conclusions of this author will be given, in reference to the differential diagnosis between the true *alternans* and the *pseudoalternans*. These conclusions are:

1. There occurs in the human subject a true cardiac alternation; a rhythmic sequence of stronger and of weaker systoles of the auricles and of the ventricles.

2. A disturbance of rhythm is not manifest at the heart, but only in the pulse, where the smaller pulse-wave seems to be somewhat delayed.

3. This delay in the pulse is not due to impaired conductivity, but to a prolonged contraction time and to a slower transmission of the small wave in the artery.

The prolonged contraction time is caused by the more sluggish course of the smaller systole and by the greater resistance in the aorta at the time of the smaller systole.

4. If an extrasystole appear in a *pulsus alternans*, the alternation may become so accentuated that the second pulse intermits.

5. There is but a *single* form of the *pulsus alternans*, the one with the *delayed* smaller wave. If the smaller wave appear at the normal time or even somewhat before it, the pulse is a *pseudoalternans*, due to extrasystoles.¹

6. In true *alternans* the delay of the smaller pulse destroys the equality and simulates a disturbance of rhythm; in *pseudoalternans* it destroys the disturbance of rhythm and simulates equality.

In view of Volhard's studies, a figure in the last edition must be regarded as a *pseudoalternans*, and has consequently been replaced by one of Volhard's curves (Fig. 62, p. 142), which, from the accompanying cardiogram, must be designated as a true *alternans*.

SPHYGMOMANOMETRY (TONOMETRY)

THE DETERMINATION OF THE ARTERIAL MAXIMUM PRESSURE (SYSTOLIC PRESSURE)

The sphygmograph furnishes only relative information of the height of the arterial pressure; hence von Basch² attempted to construct an instrument to measure the arterial pressure upon the living human body. He succeeded, approximately, with the sphygmomanometer. Potain has since modified von Basch's modernized instrument.

Von Basch attempted to copy the method of estimating pulse "tension" with the finger (p. 115) by measuring instrumentally the amount of pressure required to suppress the pulse-wave. Waldenburg, Talma, and Verdin had attempted to obliterate the pulse in the artery by compressing the artery by weights or springs. The size of the surface pressed upon was neglected in these experiments, so that their results are of no particular value. To obviate this difficulty, von Basch devised a so-called air pelotte, which he connected to a spring manometer by means of a rubber tube. The pelotte consisted of a short hollow metal cylinder, each end of which was capped with a thin rubber membrane. With this mechanism the size of the surface pressed upon makes no difference; the manometer reading will always be the same, for, according to hydrostatic laws, the amount of pressure indicated by the manometer is that exerted upon each point of the surface of the pelotte.

¹ If the difference in sizes of the pulse be very slight, the intervals even in true *alternans* may nevertheless be approximately equal, *i. e.*, the delay in the pulse may be inappreciable.

² Berlin. klin. Woch., 1887; Arch. de physiologie, 1889, Ser. 5, vol. i, p. 556, and vol. ii, p. 300.

Von Basch's Sphygmomanometer.—Fig. 91 represents a modified form of the instrument: *A*, the manometer; *B*, the pelotte; *C*, the connecting tube. By means of the cock, *D*, the entire system is filled with air under a low pressure,¹ so that the pelotte is but slightly tense, and the two closing members bulge a trifle.

The employment of this instrument is very simple. The course of the artery to be examined is first marked upon the skin; one of the bulging membranes of the pelotte is placed upon the artery, and the manometer is laid upon the bed at the side of the patient. The examiner then attempts to estimate the amount of pressure (read upon the manometer scale) necessary to obliterate the pulse peripheral to the pelotte. This he does by palpating with one finger, while with another he prevents any anastomotic pulse from entering the artery. This method will determine the arterial pressure. The result will perhaps be more accurate if the manometer be read at the moment when the pulse reappears after the pressure has been gradually diminished. The measurement is usually made upon the radial artery, although the temporal may also be employed. To utilize the results obtained the difference in level between the artery and the heart must be given. Since the arterial pressure varies with the position of the body, the attitude of the patient during the measurement (standing, lying, sitting) should also be stated. The method is, of course, entirely subjective, as its accuracy must depend upon the examiner's sense of touch. To obviate this difficulty, v. Basch has attempted to substitute the sense of sight. A rubber band is rather loosely placed over the radial artery, and a small pin stuck in it, so that the excursions of the pin are plainly visible. If the pin stop moving, the pulse is considered absent. According to the author's experience, this device is not always successful. In order to make the measurement more objective, the author prefers the combination of the Riva-Rocci method with the employment of the sphygmograph. (See p. 175.)

Fig. 91.—Von Basch's sphygmomanometer.

Two factors combine to prevent this method from measuring the true arterial pressure accurately. In the first place, the wall of even an empty artery remains open, so that a certain, though small, amount of the pressure exerted represents that employed to compress the arterial tube; and, in the second place, the tissues covering the artery must interfere to a slight extent with the accurate application of the pelotte, so that the instrument must register a somewhat higher pressure than actually exists.

Von Basch's experiments, however, show that both these factors combined cannot cause a deviation of the real values from those recorded of more than about 10 to 15 mm. Tigerstedt² gave a very unfavorable opinion of the value of this method, because he found a much greater deviation. In the first three editions of this book the author shared his view, but feels obliged to withdraw his criticism since he has used the improved air pelotte, as illustrated in Fig. 91, together with his own manometer. As a matter of fact, the results given by the old pelotte were not very reliable, for reasons which cannot be here given in detail. The temporal artery is the most conveniently situated for this measurement; the radial next, since it is compressible against the lower end of the radius. In the former von Basch found that the normal pressure varied from 99 to 120 mm. Hg; in the latter, from 110 to 160. The author's own estimations at the radial, in healthy adults with the new pelotte (see below), have usually been about 150 mm. In a pathologic increase of pressure, values over 250 mm. may be obtained. Potain's investigations (*loc. cit.*) show that these figures correspond to the maximum pressure variations during a pulse-wave, i. e., to the systolic pressure.

¹ Von Basch formerly filled the cylinder with water. Air was first employed by Potain, and has the advantage of doing away with hydrostatic pressure, and so enabling us to disregard the level of the manometer in reference to the pelotte.

² *Lehrbuch der Physiologie des Kreislaufes*, Leipzig, 1893.

Another reason to doubt the accuracy of this method is the following: since dynamic processes (that is, moving masses) are chiefly concerned, we must consider the vital power of the pulse-wave according to the laws of the hydraulic press. Now, it is well known that when a current is checked by some obstruction, its lateral pressure above the obstruction is far greater at the moment of checking than the lateral pressure of an unobstructed stream. This arises from the transformation of the pressure of velocity into lateral pressure. The hydraulic press or ram depends upon this principle. This is true not only of uniform currents, but also of the wave-like impacts of the arterial pulse. Consequently a large pulse-wave, even with low arterial pressure, will force its way through under the compressing pelotte, owing to the greater amount of "energy," while a smaller pulse-wave, even with higher arterial tension, will be completely obstructed, because the latter possesses less energy. Again, the portion of the wave which passes through under the pelotte will be felt longer if the pulse be large than if it be small and hard to feel, even though of high tension. In one of the author's works,¹ however, he has shown that the sources of error² of this method, connected with the energy or volume of the pulse-wave, are not sufficient to impair materially its value for the determination of the systolic or maximal blood-pressure. Potain, as mentioned above, has also found that the method in question indicates the so-called maximum, i. e., the cardiac systolic pressure. This is in accord with the view just expressed, that the energy or volume of the pulse-wave has no essential influence upon the disappearance of the peripheral pulse.

From the discussion upon the determination of the minimum pressure by means of the Riva-Rocci method (see p. 175) it will be seen that von Basch's instrument may be likewise employed for the determination of the minimum blood-pressure if we determine the pressure of the pelotte under which the peripheral pulse commences to become smaller. This procedure, however, is of only approximate value, and considerable experience is requisite to determine this exact moment with any degree of certainty.

Fig. 92.—Sahli's pocket sphygmomanometer

Sahli's Pocket Sphygmomanometer.—The author has made what he believes to be an improvement in von Basch's instrument by increasing the diameter of the air pelotte from scarcely 2 cm. to about 3 cm. This greatly aids us in securing pneumatic pressure upon the artery; while with the small pelotte of von Basch there is danger of compressing the vessel by the resistant portion of the caoutchouc near the rim of the pelotte or by the rim itself.

As it has also been the author's experience that the metal manometer of the shops is not very accurately graduated, and that, although it may be correct originally, the values of the scale gradually change, he has constructed a pocket mercury manometer, which may be easily transported, is absolutely correct, and has the additional advantage of being cheap.³ This manometer may also be employed for any other manometric method, in the Riva-Rocci sphygmomanometer, for example. (See p. 166 et seq.) The instrument is illustrated in Fig. 59, and consists simply of a U-shaped manometer, one branch of which can be elongated by inserting a

¹ Ueber das absolute Sphygmogram u.s.w., Arch. f. klin. Med., 1904, vol. lxxxI.

² Although the author's statements refer to the Riva-Rocci method, they are equally true for the pelotte method, since there is no difference in principle between the two.

³ The instrument is manufactured by the optician Büchi, in Bern

glass tube, the connection being accurately ground. The caliber is sufficiently large to exclude the disturbing element of capillarity, and yet not large enough to require a great quantity of mercury. Owing to the accurate adaptation of the two tubes, it is unnecessary to use the greasy materials usually employed to secure the perfect adjustment of glass stop-cocks, and the mercury is consequently kept in much better condition. When the instrument is to be employed, the extension *a c* is inserted, and a pneumatic pelotte, such as that of von Basch's instrument (preferably the enlarged form, as described upon p. 164; see Fig. 91) is connected with *b* by a tube. The pressure exercised upon the artery by the pelotte is transmitted to the shorter arm of the manometer. The elongated arm is so divided that it gives the pressure directly in centimeters, every half-centimeter being marked as a unit. In such a manometer, as is well known, the pressure is obtained by multiplying the height of the ascending column by two, because the mercury falls exactly as far in one branch as it rises in the other. The manometer must be accurately filled with mercury to the zero mark. The ampulla *d* is constructed to prevent forcing the mercury out of the shorter branch by a sudden diminution of pressure, and the ampulla *c* acts in a similar manner if the pressure be suddenly increased by careless manipulation of the pelotte. The instrument may be packed for transportation by removing the extension tube *ac*, plugging the opening *a* with a tightly fitting cork, and closing the other end by turning the glass stop-cock. Rubber corks are not suitable because the formation of mercuric sulphid would dirty the glass tube. A convenient case carefully cush-

Fig. 93.—Sphygmomanometer (after Riva-Rocci).

ioned to prevent breaking is supplied and is made large enough to hold a pelotte as well. With such an instrument one determines values which are almost exactly in accord with those obtained with Riva-Rocci's instrument. In fact, the former values are even more reliable, because they are obtained from a superficial artery and so almost entirely uninfluenced by soft parts.

Since the mean blood-pressure is so important for diagnosis, as well as for determining the efficiency of certain therapeutic agents, it is very fortunate that so many physiologists have recently turned their attention toward devising some simple and accurate method of measuring it. Such methods have been described by Mosso, Hürthle, v. Frey, Riva-Rocci, and Gärtner.

The Riva-Rocci and the Gärtner instruments are the only ones which have proved to be practically valuable, and are, therefore, the only instruments described in this edition.

*Riva-Rocci's Sphygmomanometer.*¹—Its principle is similar to that of von Basch's. It measures the amount of pressure necessary to obliterate the pulse peripheral to a point of constriction. A pneumatic pressure is used as in von Basch's instrument. The practically important modification consists in substituting for the pelotte used to press upon the artery a pneumatic cuff (*a*, Fig. 93), which encircles the upper

¹ Riva-Rocci, *Un nuovo sfigmomanometro*, Torino, 1896; *Frascati e Comp. Technica della sfigmomanometria*, *Gaz. Med. di Torino*, 1897, Nos. 9 and 10.

arm, and the cavity of which connects with a rubber bulb. Since the upper arm contains only a single bone, inflation of the cuff will interrupt all the arterial supply to the forearm in a perfectly equal way.

The cuff should be made of some firm mackintosh cloth, or, if of elastic rubber, it should be covered, at least on the outside, with some material which will not stretch. This is to prevent the loss of a part of the pressure from any eccentric inflation or distention of the wall. Fig. 93 represents the original form of the apparatus.

[In America, Cook rendered a great service by so modifying the Riva-Rocci apparatus as to make it inexpensive and portable,¹ thus securing for it a much more extended application. His instrument so closely resembles its original in the technic of its use that it needs no further description.—Ed.]

Fig. 92 represents a convenient modification of the instrument used by the author. The portable manometer (Fig. 94) is connected with the bulb and the cuff by a T tube. Büchi (Bern) supplies this apparatus; the cuffs were designed by the author. The cuffs come in two widths, 6 and 8 cm., and are closed by a clamp employing a lever instead of the rather clumsy screws of the original apparatus. Of late a simpler and cheaper model, something like the American one, has been used, in which the cuff is attached by a leather or canvas strap, passing around it and

Fig. 94.—Riva-Rocci sphygmomanometer as modified by Cook.

fastened by a buckle. The broader cuffs are now preferred, not so much on account of v. Recklinghausen's criticism of the narrower one (see p. 168), as because, if the arm be very soft and fat, a high pressure will be apt to make the inner layer of the narrow cuffs bulge out to the side along the edge. The broad cuff may also be used to advantage in sphygmobolometry. (See p. 180.)

The patient's upper arm is inserted into the cuff (a). The latter is connected with a mercury manometer (b), or the author's portable manometer (Figs. 92 and 94), and through it with a double rubber bulb (c). By pumping at c the cuff can be made to encircle the upper arm snugly, but without much compression, and the amount of pressure employed can be read in millimeters of mercury upon the vertical tube of the manometer. This pressure is increased until the radial pulse disappears. The method was tested by Riva-Rocci on animals; and by Gumprecht,² on the human cadaver: and, according to them, if the muscles be well relaxed, the circumstance that the compression is applied through thick muscles does not invalidate the result. Fellner's and Rüdinger's³ experiments on dogs were less favorable.

¹ H. W. Cook, Jour. Amer. Med. Assoc., 1903, vol. xl, p. 1199.

² Zeit. f. klin. Med., 1900, vol. xxxix, Parts 5 and 6.

³ Ibid., vol. lvii, Parts 1 and 2, p. 125.

They showed that the maximum and minimum pressures obtained by the Riva-Rocci method differ from those measured directly by a manometer, sometimes by as much as 50 or 70 mm. Yet the difference between the maximum and the minimum pressure ("pulse pressure," height of the absolute sphygmogram) agrees with that obtained by a direct manometer.¹ The author believes that these experiments on dogs do not furnish satisfactory data for conclusions as to the value of the procedure with human subjects, as the shape of the dog's leg is probably a disturbing factor and so, too, very likely is the hairy surface.

The maximum or systolic pressure is given by the reading at the moment of the disappearance of the pulse, the same as with von Basch's instrument. (See p. 164.) Normal adults furnish with the Riva-Rocci apparatus a value of 140 to 150 mm. Hg²; and arteriosclerotics and nephritics up to 230 to 250 mm., or even higher. For control it is well to raise the pressure beyond the point at which the pulse cannot be felt, and then, when, as a result of the yielding of the rubber tubes³ and connections, the pressure falls slowly, the point is noted at which the pulse begins to appear again. In this way the attention is not distracted by the need of pumping, and the method is still more objective and quite exact. The author has frequently attempted to supplant the palpation of the pulse by the objective method of sphygmography, making short curves at different pressures until the needle makes but a straight line. It has advantages in demonstrating to a clinic. One caution should be added. Pronounced congestion, pain, and even cutaneous hemorrhage may result from employing the instrument to measure very high pressure, *e. g.*, above 230 mm.

The author has found the results obtained by Riva-Rocci's instrument agree very closely with those obtained by von Basch's method as modified by him. (See p. 165.) Apparently the two procedures are equally accurate. (For the measurement of the minimum pressure with Riva-Rocci's instrument see the section on the absolute sphygmogram, p. 174.)

Led by v. Recklinghausen,⁴ a number of writers have pointed out that the cuff of Riva-Rocci's original instrument is too narrow. They came to this conclusion from the fact that different values are obtained when a wider cuff is employed. It is clear that if the cuff be too narrow, the inflation produces a marked distortion, both of the cuff itself and of the surface of the arm, which endangers the transmission of the aërostatic pressure, since a certain fractional part of the manometric pressure is consumed in producing the aërostatic tension of the cuff and the tension of the tissues pressed upon. The cuff of the original Riva-Rocci instrument was 4.5 cm. in width. These authors now demand a cuff 32 cm. wide. This makes the instrument more clumsy. Additional errors also arise from the fact that such a broad cuff does not act upon an approximately cylindric surface, owing

¹ In opposition to this view, according to the author, is the statement of these investigators that the Strassburg blood-pressure quotient (ratio of the pulse pressure to the maximum pressure, see below) can be determined accurately by the Riva-Rocci method; although these figures must be decidedly influenced by the deviation of the maximum pressure.

² The blood-pressure in normal children has been carefully studied by Oppenheimer and Bauchwitz; see *Arch. f. Kinderheilkunde*, vol. xlii, p. 145. The following values were obtained by the author with Riva-Rocci's instrument, and are quoted here because the above-named investigators do not furnish exact normal figures derived from a large series of examinations:

Age.	Height.	Blood-pressure.
12 years	136 cm. (54 in.)	112 mm.
10 "	125 " (49 ")	110 "
4 "	100 " (40 ")	110 "
8 months	73 " (29 ")	96 "
8 weeks	61 " (24 ")	92 "
6 "	53 " (21 ")	90 "
6 "	51 " (20 ")	80 "
5 "	59 " (23 ")	84 "

³ In case the apparatus is absolutely air-tight, a capillary escape tube may be inserted between the cuff and the bulb (see section on Sphygmobolometry, p. 181), and thus air be allowed to escape gradually by means of a glass stop-cock.

⁴ Recklinghausen, *Arch. f. exp. Pathol. u. Pharm.*, 1901, vol. xlii, parts 1 and 2; Hensen, *Deut. Arch. f. klin. Med.*, 1900, vol. lxxvii.

to the irregular contour of the arm. Martin¹ has found that a cuff 10 cm. in width suffices for all cases. In the author's opinion a great deal depends upon the material of which the cuff is made, upon the flexibility of its outer layer, and upon the manner in which it is applied.² The author has treated this subject more freely in his article on the absolute sphygmogram.³ The very wide cuffs are particularly

Fig. 95.—The author's sphygmomanometer in use, according to Riva-Rocci's method

useful in sphygmobolometry. If the cuff be emptied and applied accurately to the skin without the exercise of any pressure, cuffs only 5 to 6 cm. in width remain so

¹ Münch. med. Woch., 1903, No. 24, p. 1021.

² Neglect of these considerations may explain the great divergence of opinion regarding the value and practicability of the different widths.

³ Arch. f. klin. Med., 1904, vol. lxxi.

flat during inflation that the transmission of the pressure is complete and the results are as accurate as they can well be from the nature of the procedure. We should banish the illusion that this procedure equals the accuracy of manometry upon the exposed and divided artery.

[*Hill and Barnard's Sphygmometer*¹—This instrument appeared in England a little after Riva-Rocci's, and uses the same method of circular compression. It does not, however, measure the pressure required to obliterate the pulse (systolic or maximum pressure), but, like Mosso's, the point of maximum pulsation (diastolic or minimum pressure). This is accomplished by the employment of a delicate spring tambour, graduated in mm. Hg., as the manometer. Fig. 96 shows the apparatus. The cuff, a hollow bag, 4.5 cm. wide, with an outer leather armlet, is buckled around the arm, and connected with the manometer by a screw-joint. The pressure is then raised by means of the hand-pump until the needle shows diminishing excursions on the dial. Then, by unscrewing a valve in the stem of the pump, the pressure is allowed to fall gradually, while the needle is closely watched. Its oscillations increase for a time to a maximum, then, after remaining the same for a short time, rapidly decrease. The last point at which they remain maximal represents the minimum arterial pressure, as already described. Hill thought that the midpoint of maximum oscillation was equivalent to the mean arterial tension, but this has been proved inaccurate. The instrument is well constructed, light, and compact. It has two drawbacks. One is the narrowness of

Fig. 96.—Hill and Barnard's sphygmometer.

the cuff. The other is, that so delicate a manometer needs constant standardizing by comparison with a mercury one, and soon becomes inaccurate.—Ed.]

*Gärtner's tonometer*² depends upon a similar principle. It estimates the pressure which is required to interrupt the peripheral circulation. Gärtner makes use of the color of the tip of the finger instead of feeling the pulse to determine the condition of the peripheral circulation. His instrument consists of a small pneumatic compression ring, whose cavity is connected with a mercury or spring manometer and with a rubber bulb. The pneumatic ring is constructed of a metal hoop 1 cm. high and 2½ cm. in diameter. A rubber membrane lines this hoop, and with the latter surrounds an air-space communicating with the manometer and bulb. The pneumatic ring is first slipped over the second phalanx of the little finger without pressure. The projecting end phalanx is then made bloodless by a rubber compressor like a glove-finger, or by a ring cut out of a rubber tubing, rolled upon the finger as far as the pneumatic ring. This compression is kept up until the pressure in the pneumatic ring has been raised by means of the bulb sufficiently to keep the blood from returning to the finger, then the compressor is removed. The finger-tip now appears bloodless. By gradually releasing the pressure from the rubber bulb the finger becomes colored again. As a matter of fact, the finger be-

¹ Hill, L., Barnard, H., Brit. Med. Jour., 1897, vol. ii, p. 904. Made by J. Hicks, London; agents for the United States, Oelschlager Bros., 110 East 23d St., New York City.

² G. Gärtner, Ueber einen neuen Blutdruckmesser (Tonometer), Wien. med. Presse, 1899, No. 26. L. Schulmeister (Vienna) and F. Hegershoff (Leipzig) make the instrument.

comes deeply colored, and so facilitates the differentiation. This is because the veins will still be compressed at the moment the digital arteries open under the arterial blood-pressure. This pressure at which the blood again streams into the finger can be regarded as equivalent to the blood-pressure in the digital arteries. In cases where the capillaries of the finger-tip are much contracted, it may happen that the finger-tip will not be properly colored after the release of the pressure on the arteries. In such cases Gärtner accomplished his purpose by relaxing the tonus of the fine vessels by producing an artificial congestion from a pressure of 20 to 40 mm. Hg with the pneumatic ring for a half minute, and so paralyzing the vessels just before repeating the test. Gärtner assumes that the pressure in the small digital arteries differs but little from that in the radial. Of course, the measurement will be decidedly influenced by the height of the fingers, so that he recommends that the test be undertaken with the fingers at the height of the heart. The normal pressure values Gärtner has estimated vary between 90 and 105 mm. These are less than those obtained either by von Basch's or Riva-Rocci's method, a fact which militates against Gärtner's original assumption that the pressure at the finger-tips does not vary essentially from that in the radial artery. Another objection to the method is that the readings are decidedly influenced by the resistance of the tissues of the finger-tips. This resistance is very different in a laborer's hand and in a lady's hand. In the writer's opinion, these sources of error are so considerable that it discounts the value of the entire procedure, except in determining the variations of pressure in the same individual at different times. Certain technical modifications of this method¹ do not obviate this chief fault. It may be added that Gärtner's method of employing the sense of sight may also be used in connection with the Riva-Rocci instrument, by encircling the arm with an Esmarch bandage before the procedure.

Von Recklinghausen's Blood-pressure Apparatus.—This instrument has been used to a considerable extent recently. It is constructed according to the principles of Riva-Rocci's; and differs from the other clinical blood-pressure instruments chiefly in the construction of its manometer, which the inventor calls a *tonometer*. This, a metallic manometer, consists of a short, lightly curved bourdon tube, shallow oval in cross-section. The effect of changing pressure upon its inner wall alters its shape, and transfers its excursions to an indicator, which in turn registers the pressure values upon a dial. If, as in all metallic manometers, the zero point be dislocated, the indicator can be properly adjusted by means of a screw. This device, and a more careful construction, distinguish the instrument from the other ordinary metallic manometers (von Basch's and Potain's, for example) to its own advantage. The latter have frequently been criticized because their accuracy is gradually impaired through a loss of elasticity. Von Recklinghausen recommends controlling the instrument from time to time by comparing it with a mercury or water manometer. The instrument is supplied with a conveniently arranged cuff, 13 cm. wide, covered on the outside with canvas. The cuff is distended not by means of a rubber bulb, but by means of an air-pump fixed with the foot and worked by hand. To preserve sufficient excursions of the indicator with the oscillating pressure measurement the pump is not connected directly with the cuff and the manometer, but a capillary metallic tube is interpolated so that the pump chamber does not diminish the pressure oscillation. The tonometer is graduated in centimeters of water, instead of millimeters of mercury. Von Recklinghausen considers that this conforms better to the gram centimeter system recently introduced in physics, and he finds a practical value in this sort of graduation, because the specific gravity of water varies so little from that of blood, so that a simple addition or subtraction corresponding to different levels is sufficient for a rapid calculation of the pressure at any point of the vascular system. The low pressure values in the veins and capillaries are naturally more easily measured by water than by mercury pressure. To calculate the pressure found in accordance with the height of the heart, von Recklinghausen considers that the latter corresponds to a sagittal axis of the thorax drawn through the lower end of the sternum. When measuring in the sitting posture, the middle of the cuff upon the arm corresponds approximately with the height of the heart, which obviates the necessity for hydrostatic calculation. The disadvantage of this instrument is, however, that the figures differ from the usual values expressed in millimeters of mercury, and the mercury manometer will probably remain the instrument of choice for blood-pressure work. For the sake of comparison with the mercury manometer, it would be desirable to add to the instrument a scale graduated in millimeters of mercury. This instrument can be utilized just as any other manometer for the palpatory measurement of the blood-pressure. (See p. 117.) For

¹ See Martin, Münch. med. Woch., 1903, No. 24, p. 1021.

this, von Recklinghausen especially recommends the so-called oscillatory measurement, making use of the size of the oscillations which the manometer exhibits under the influence of the pulse. The minimum pressure is estimated in this way, according to von Recklinghausen, and corresponds to the lowest pressure upon the cuff, which makes the indicator show the greatest excursions. If the pressure be increased, the point at which these maximum excursions begin is ordinarily sharply marked;

Fig. 97.—Stanton's sphygmomanometer.

sometimes, however, the oscillations increase indistinctly, even sufficiently to extend over 10 to 15 cm. of water. The maximum pressure is also estimated by these oscillations, and corresponds to the point at which the large oscillations produced by increasing pressure become suddenly smaller again. This boundary point, however, is less distinctly marked, and, therefore, von Recklinghausen recommends for estimating the maximum pressure this method, and in conjunction with it the old pal-

patory method (estimation of the cuff pressure at which the radial pulse disappears). His apparatus is also supplied with a device (tonograph), by means of which the oscillatory measurement can be represented graphically. There is also furnished a peculiar ring-shaped rubber pelotte, closed in the middle with a glass plate for vision. By means of this contrivance von Recklinghausen estimates the pressure at which the veins collapse (*venous pressure*), or at which the skin becomes pale from compression of the capillaries (*capillary pressure*).

Stanton's Sphygmomanometer.—Stanton's¹ instrument is shown in Fig. 97. The manometer consists of a metal cistern (C) connected with a glass upright tube and scale (D), which can be unscrewed for carrying. The armlet is a hollow rubber bag, 4 in. (10 cm.) wide and 16 in. (41 cm.) long, closed at both ends, and attached to an

Fig. 98.—Janeway's sphygmomanometer

outer cuff of thick canvas, reinforced by tin strips. A wider cuff, 6 in. (15 cm.), is supplied if desired. A single rubber bulb is used for inflation. At A is a stop-cock, and at B a screw valve for the gradual lowering of pressure. It is a portable, convenient, and durable clinical instrument.

Janeway's Sphygmomanometer (Fig. 98).—Its special feature is the portable U-tube manometer attached to a case, into which it folds for carrying. The armlet

¹ W. B. Stanton, Univ. of Penna. Med. Bull., 1903, vol. xv, p. 466.

is a hollow rubber bag, 12 x 18 cm., loosely covered and attached to an outer leather cuff, 15 x 33 cm., which fastens by two straps with friction buckles. For inflation a Politzer bag with valve is used. *E* is a stop-cock provided with a needle valve, by which the pressure can be reduced gradually. It is a portable, convenient clinical instrument.

Repairs to the last named are frequently necessary, and the original cost of both these instruments is greater than desirable for an instrument so generally employed. Any one can construct a perfectly satisfactory apparatus for office and ward work at a cost of less than five dollars by purchasing a good cuff,¹ bulb, rubber tubing, glass T-tube, and U-tube manometer. The latter can be fastened to an upright board with a scale marked upon it, and nailed to another horizontal board.

*Erlanger's sphygmomanometer*² is, undoubtedly, the most accurate and valuable instrument yet constructed. It gives readings both of systolic (maximum) and diastolic (minimum) pressure, and therefore makes possible the calculation of exact mean arterial pressure. Fig. 99 shows the apparatus in perspective. The cuff is 12 cm. wide.

Besides the manometer, compressing armlet, and inflator it contains a somewhat elaborate reading mechanism and kymographiondrum. This mechanism consists of the tambour, the interior of which is connected with the air-chamber inside the glass bulb *G*. This air-chamber has no other openings while the record is being made, but automatically connects with the outer air through the tube *E* and the stop-cock *C* when rapid changes in pressure are made, which might damage the tambour. The pulse-waves are transmitted through the tube to "*PS*" and cause variations in volume of the rubber bulb *B*. These pulsations of *B* are, of course, reproduced by the air within *G*, and thus carried to the tambour, which inscribes them on the smoked cylinder. The purpose of the rubber bulb *B* is to shield the tambour from too sudden and great variations of pressure. The stop-cock is an important mechanism, but cannot be described intelligently without mechanical drawings. It is easily understood from the instrument itself. Unfortunately, this apparatus is too bulky to be carried far, and is more complicated than desirable for strictly clinical work. For purposes of physiologic experiment on human beings, and whenever very accurate readings of both pressures are desired, it should be the choice. Ed.]

Fig. 99.—Erlanger's sphygmomanometer.

The Diagnostic Signification of the Measurement of the Systolic Arterial Blood-pressure

The introduction of these methods of estimating arterial (maximum) blood-pressure into clinical work gave promise of much assistance in functional diagnoses directly applicable to treatment. There arose, in particular, a tendency to settle the very important functional diagnosis of the existence of stasis by means of the height of the arterial (maximum) pressure, and to regard the existence of a high pressure as proof of a good circulation, an efficient heart action, and a contraindication to digitalis, and that of a low blood-pressure, on the contrary, to the use of the drug. This conception was, however, soon proved to be erroneous, and the author was the first to disentangle these complex relations by creating the idea of "*high-pressure stasis*." He showed at the Congress for Internal Medicine (Berlin, 1901)

¹ [Galante Fils, rue de l'Ecole de Médecine, Paris, make the most convenient and durable cuff which I have used. Ed.]

² Erlanger, J., Amer. Jour. Physiol., 1904, vol. x, Proceed. of Amer. Physiol. Soc., p. 14.

that the presence of a high arterial blood-pressure does not exclude the coexistence of stasis (inefficient heart action, retarded circulation, abnormal distribution of the circulating blood); and that a large group of cases with stasis, on the contrary, do exhibit a high maximum pressure: (1) for the most part, cases in which a primary increase of resistance in the vessels causes the stasis, *e. g.*, in arteriosclerosis and chronic nephritis; and (2) other cases in which the dyspnea caused by the stasis leads to the stimulation of the vasomotor center and therefore secondarily causes a high blood-pressure. This, the author's "high-pressure stasis," in which a diminished heart efficiency exists in the presence of high arterial pressure, is an apparent paradox, but it may be thus explained: with the increased vascular resistance even very small systoles suffice to maintain the high blood-pressure, and if the systoles be small, the high pressure is perfectly consistent with insufficient heart power, because the heart work of a systole is measured by multiplying the volume of blood expelled by the resistance to be overcome. This reasoning indicates that a high blood-pressure is not always a contraindication to the use of digitalis which increases the heart power and improves the systole. Besides practical experience with such cases of "high-pressure stasis" proves that digitalis lowers rather than raises their blood-pressure. Neither is a low blood-pressure always a sign of a poor circulation. Fever, where the circulation is probably accelerated, is an instance in point; because very likely an increased and exceptionally good circulation may accompany even a low blood-pressure provided that relaxation of the vessels diminishes the resistance. In fever, *e. g.*, in pneumonia, a low pressure in itself is by no means an indication for the use of digitalis, although one may employ it as a prophylactic measure.

The determination of blood-pressure is, therefore, evidently not so valuable in functional diagnosis of the circulation as was originally expected. Nevertheless, its measurement does possess some diagnostic significance, as, for example, the frequent occurrence of high pressure in chronic nephritis and of low blood-pressure in fever. In febrile conditions the height of the blood-pressure has a certain prognostic significance, in that the extent of the lowering corresponds in some measure to the severity of the constitutional disturbance. This is especially the case in pulmonary tuberculosis, where the toxemia often shows itself in a lowering of the blood-pressure to 80–100 mm. before causing fever. This can be easily explained by the fact that the febrile manifestation is often retarded on account of the small amount of combustible material furnished by a reduced diet. (See p. 71.)

The "absolute sphygmogram" (see the following section), and in particular the comparative determination of maximum and minimum pressures, furnish somewhat more valuable information, but by no means as valuable as the beginner would have believed.

THE ABSOLUTE SPHYGMOGRAM

The Significance of the Simultaneous Determination of the Systolic (Maximum) and the Diastolic (Minimum) Arterial Blood-pressure; the So-called "Pulse-pressure" (Height of the Absolute Sphygmogram) and the Blood-pressure Quotient

We have already pointed out in the section on Sphygmography the imperfections of this method. The data derived from the form of the curve are by no means satisfactorily definite. The significance at first attributed to the secondary elevations (Landois, Marey, and others) has been disproved by the later investigations of v. Frey and Krehl. (See p. 133 et seq.) Even the general form of the sphygmogram cannot be easily interpreted since (1) the form of the summit of the curve is influenced greatly by reflected, partially retreating waves, and (2) the height of curve depends on many adventitious factors (mode of application of the sphygmograph, tension of its spring, flexibility of the arterial wall, width of the artery, frequency of the pulse, etc.). Consequently the height of the sphygmogram not being a reliable criterion, the method furnishes but little useful information in regard to the size of the pulse or of the pulsatory changes in arterial pressure that are, of course, points of greatest clinical interest; nor does it afford any means of determining the manner of the rises or drops of such pressure. It throws therefore but little light upon the question of the celerity or tardiness of the pulse. For instance, it is frequently difficult to demonstrate the *pulsus celer* from the sphygmogram of a patient in whom its presence is absolutely proved by palpation, the capillary pulse, and the tone of the arteries.

This leads to attempts to obtain the excursions of the pulse by the direct measurement of the maximum and the minimum pressures. For a criticism of the experiments

made with this purpose by Potain,¹ Hensen,² and von Recklinghausen,³ see the author's article on the absolute sphygmogram.⁴ In the latter the author reported a new method of obtaining the minimum pressure, which he afterward found had been previously described by Janeway,⁵ and which was later, independently of Janeway's communication, worked out by Masing,⁶ Strassburger,⁷ and himself.⁸ The fact that four writers should independently have fallen upon the same method ought to speak well for the correctness of its principle. This method consists in measuring both the maximum and minimum pressures by means of the ordinary sphygmomanometer. The maximum pressure corresponds to that which obliterates the arterial pulse, the minimum pressure to that under which the pulse first begins to decrease in size. All four authors mentioned used Riva-Rocci's instrument, and all but Strassburger, who employed palpation, determined the moment when the size of the pulse began to decrease, by making sphygmograms from the radial artery. For a proof of the assumption that the minimum pressure corresponds in time to the moment when the pulse becomes smaller, see the author's article mentioned above. Evidently the instant the pulse becomes smaller, the compression of the bag must begin to block the transmission of the pulse-wave from the brachial to the periphery; and this hindrance must act not only in a beginning compression of the artery, naturally corresponding in time to the moment when the arterial pressure is lowest, i. e., the valley of the wave; but as soon as the pulsation increases the pressure, the hindrance (compression) is again overcome. When the compression is still further increased, the pulse-wave will completely disappear at the periphery, and at this moment the maximum or systolic pressure can be read upon the manometer scale. (See p. 164, et seq.) The author in the above-mentioned article has also supported the assumption that this is the actual maximum pressure.

One difficulty met with in this procedure is that, when the cuff of the Riva-Rocci apparatus is inflated, the resulting venous congestion elevates the spring of the Jaquet's sphygmograph. This raises the tracing needle and so shortens the ordinates of the curve. Moreover, the spring being lifted somewhat does not truly appreciate the pulse-wave. Hence with increasing pressure in the cuff the venous pressure gradually diminishes the height of the wave. It is difficult to distinguish such a lowering of the curve, due to a secondary effect of the apparatus, from that caused by the initial compression of the artery.

This difficulty may be corrected, at least in part, by applying the sphygmograph as tightly as possible in the beginning, since then the swelling of the extremities caused by the venous congestion will not materially increase the pressure against the frame and so raise the spring. To prevent the artery from being compressed by this congestion the author fastens a "cross bow" to the sphygmograph frame to which the straps are applied, and this device (already described upon p. 125) allows the artery to lie in a sort of hollow trough and prevents any pressure despite the fact that the wristlet is buckled on very tightly. The cross bow is so arranged that it can be applied or taken off at will. A satisfactory substitute for this cross bow can be improvised by slipping under each arm of the frame at the upper extremity of the wristlet a rounded piece of cork. Elevation of the curve dependent upon inflation of the cuff can be much reduced by thus tightly buckling the cuff, or even wholly prevented if we inflate the cuff more rapidly than the arm can swell. The direct pressure of the radial artery's *venæ comites* upon the spring inevitably produces some little rise in the curve in most instances. If slight, however, this is of no disadvantage, because, in spite of it, the reduction of the height of the pulse-wave, by increasing the pressure in the cuff, is easily recognizable (Fig. 100, at the mark 100.) To decide whether this reduction depends entirely on the raising of the curve, a curve may be traced without pressure in the cuff, the position of the recording needle being gradually raised by the screw. This will show what influence the raising of the curve in and of itself has on the height of the single pulse-wave. Ordinarily, no effect is visible so long as this rise is not too great. Moreover, before each increase of pressure in the cuff the clockwork of the sphygmograph may be stopped and the needle returned to its original position, so that each separate section of the curve

corresponding to a single pressure will be written at the same height as every other section. After a certain amount of practice this technic can be performed by the examiner alone, although assistance simplifies the task. The pressure is increased 10 mm at a time, and each increase indicated on the sphygmogram. These marks may be very conveniently registered by the pneumatic registering apparatus of the simplified Jaquet instrument (p. 128) or by Mackenzie's polygraph (p. 129). After the minimum pressure has been determined by noticing the place at which the height of the sphygmogram is suddenly decreased, the pressure should be increased until the curve becomes a straight line, thus indicating the maximum pressure.¹

In regard to the criticisms of this method, based upon Fellner's and Rüdinger's experiments on animals, see p. 167.

The method recommended by Janeway, Masing, and the author for estimating minimum pressure has been recently modified by K. Schliak (*Zeitschrift für physikalische und diätetische Therapie*, 1908, 1909, vol. xii). Instead of showing through the diminution of the sphygmogram the diminution of the pulse at the moment when the minimum pressure begins to compress the artery by means of the cuff, this investigator measures the excursions of the writing needle of the sphygmograph directly upon a millimeter scale. He employs the Jaquet sphygmograph, and has printed upon the end of the paper strips, vertical to their length, a millimeter scale, which he protects from being smoked by covering with a piece of paper. These strips can be obtained from C. G. Naumann, Seeburgerstrasse 57, Leipzig. After the application of the Riva-Rocci apparatus Schliak uses the sphygmograph in the ordinary way until the needle reaches the unsmoked part of the paper. He then stops the instrument and reads off the minimum pressure at the moment when, with increasing pressure of the cuff, the writing needle begins to make smaller excursions upon the scale. The maximum pressure can be read off in the same way at the moment when the writing needle makes no more excursions upon the scale. He claims that the instrument has this advantage over the graphic method recommended by Janeway, Masing, and the author, that the measurement can be repeatedly controlled without difficulty. On the other hand, the procedure loses its objective documentary character.

Fig. 100.—Determination of the maximum and the minimum pressure.

In this way we obtain the maximum and the minimum pressure of a sphygmogram in absolute values, and if we employ a sphygmograph with a time-making apparatus like Jaquet's, we can also correlate the individual components of the curve, and from all these data construct what the author calls an "absolute sphygmogram." This he understands to mean an artificial sphygmogram, which is so accurately proportioned that at every point the ordinates correspond to the pressure. In its simplest form the secondary elevations are disregarded, and the skeleton of the wave depicted, showing the shape of the main summit and the steepness of the ascending and descending limbs, i. e., the position in relations of time of the main summit to the valley ("reduced absolute sphygmogram").

¹ If the pelotte manometer be used for determining the maximum pressure, the minimum pressure may be determined, at least approximately, by obtaining the pressure by palpation the moment when the pulse-wave becomes smaller (Strassburger's method).

Fig. 101 shows the method of constructing an absolute sphygmogram upon ordinary millimeter paper. A single wave is measured along a horizontal base line, ab , each centimeter of the paper corresponding to the $\frac{1}{4}$ second of a Jaquet sphygmograph. If, for example, each pulse-wave correspond to $\frac{1}{3}$ of a second (4 cm.) (8 of the squares), a to b are marked off. From each of these points is erected a vertical ac , bd , the length in millimeters of which corresponds to the minimum pressure, e. g., 100 mm. Hg. The point e is determined from a sphygmogram of the pulse traced at high speed by measuring the distance from the foot to the summit along the horizontal. From e is erected another vertical ef , whose length corresponds to the maximum pressure. Then, by connecting c and d with f , the absolute sphygmogram in its simplest form is completed. From Fig. 101, e. g., we see at a glance that the wave began with a pressure of 100 mm. and fell to the minimum again in about 0.68 second. The difference in height between e and f ($ef-ac$) is called by the author the *height of the absolute sphygmogram* (pulse-pressure, see p. 175).

This simplified absolute sphygmogram can easily be made more elaborate by representing in similar fashion the secondary elevations and depressions of the pulse-curve. The time of each is obtained from the ordinary sphygmogram (made with rapidly moving paper), and the height computed by finding the ratio between the height of the particular elevation under consideration and the maximum height on the ordinary sphygmogram, and plotting it out on the millimeter paper. The points of the secondary apices and depressions can then be connected by a curve which should closely resemble that of the ordinary sphygmogram. There appears, however, to be no particular advantage in such an elaboration.

The absolute sphygmogram obviously gives a correct picture of the blood-pressure in the arterial system, drawn to an absolute scale. The pressure in the aorta probably differs very little from that in the radial artery, as there is so little friction to be overcome between the aorta and the wrist.¹ The rate of the pulse-wave also is practically the same, so that the absolute sphygmogram of the radial artery may without any great error be taken as that of the aorta. The practical clinical uses of the absolute sphygmogram are not, however, so extensive as might be at first supposed. It has been found impossible, for example, to draw from it conclusions concerning the strength of the cardiac activity or of the systoles (see the author's own discussion in his work already referred to). Strassburger's² criticisms, however, have not shaken the author's conviction of the correctness of his procedure. He admits that Fellner's³ conjecture concerning the influence of the vis-

cosity of the blood on the absolute sphygmogram may be correct. From the absolute sphygmogram conclusions may be drawn concerning the fluctuation of blood-pressure, the volume of blood expelled at each systole, and the condition of contraction of the arteries. The practical significance of the absolute sphygmogram lies in the possibility of a correct decision in regard to rapidity or slowness of the limbs of the pulse-wave (celerity, tardiness). In the absolute sphygmogram the difficulties arising from the unknown values of the ordinates of the curves (p. 141) are eliminated. As far as the form of a single wave is concerned, the absolute sphygmogram, instead of being simply a means of demonstration, becomes a valuable diagnostic help. It is the only means at hand to support the diagnosis of an aortic lesion by a certain demonstration of a *pulsus celer* or *pulsus tardus*. The celerity is measured by the angles which the ascending and descending limbs make with the horizontal.

It is possible that Mackenzie's differentiations of fevers into those with a more and those with a less favorable prognosis (the sthenic and the asthenic form, p. 148) based upon the more or less strongly pronounced diastolic sinking of the blood-pressure relative to the condition of diastole, may become of greater significance if the absolute sphygmogram be used. Strassburger considers that the greatest use of the absolute sphygmogram is to determine the *blood-pressure quotient*, which he defines as the quotient obtained by dividing the amount of pressure variation (the "pulse pressure") by the maximum pressure. The author's critical analysis of the absolute sphygmogram argues against the far-reaching inference which Strassburger¹ draws from the blood-pressure quotient and applies to the circulation.

THE MEASUREMENT OF THE VENOUS PRESSURE

In view of the fact that the measurement of the arterial blood-pressure alone affords by no means satisfactory conclusions regarding the condition of the circulation, it would obviously be of advantage to determine also the venous pressure. As a matter of fact, the venous pressure is quite as important a factor in circulatory conditions as is the arterial, because in accordance with hydraulic laws the rapidity of the blood-current depends upon the difference in pressure between the arteries and the veins.

Gärtner,² assuming that the veins act like manometer tubes opening into the right auricle, attempted to measure the venous pressure in the right auricle by having the patient raise his arm until a clearly visible vein, *i. e.*, one on the back of the hand, began to empty itself. The difference in height between the level of the spot observed and the right auricle gave the pressure at the auricle in centimeters of water, since this pressure is obviously what must be overcome to enable the vein to empty itself. In ordinary conditions the pressure is practically nil or even negative, so that the vein will empty itself when on a level with the auricle (at the fifth rib, in Gärtner's calculations); but in conditions of stasis the pressure is so much increased that the arm must be raised.

This method, though apparently very plausible, has certain flaws. In the first place, the pressure at the right auricle is a variable quantity, changing every moment with the phase of the heart's action, with the auricular contraction, and even with the ventricular activity. If the phenomenon in the vein be taken to mark the normal or minimum pressure at the auricle, it may be answered that the variations of the auricular pressure reach the small veins only very slowly and incompletely, otherwise we should normally always observe a venous pulse. It must, therefore, be assumed that the hydrostatic pressure in the vein works, not directly against the auricular pressure, but against a certain average pressure in those veins into which the small vein in question empties. In the second place, it is obvious that the emptying of the vein depends not merely on the pressure exerted against it, but also on the mass of blood flowing into it from the arteries. The vein is not, as Gärtner considers it, a mere manometer, because no such reflux exists in these tubes. It is obvious that in some cases, despite a low pressure at the auricle, the vein might not visibly collapse simply on account of the large amount of blood flowing into it. So that this method measures neither the pressure at the auricle nor the pressure of the vein into which the vein in question empties, especially as on account of the manifold anastomoses, it is impossible to tell what vein that would be. Although a critical analysis shows that the relations in Gärtner's method are too complicated to be employed as an accurate measure of venous pressure, yet the author does consider the phenomenon of some clinical value. If the veins of the

¹ Strassburger has more recently modified his views. Arch. f. klin. Med., vol. lxxxv.

² Münch. med. Woch., 1903, No. 47.

arm do not empty until the arm is markedly elevated, some venous stasis evidently exists, and vice versa. The author considers, however, that the jugular veins are more trustworthy witnesses to speak for venous stasis, because when they collapse, we are certain that their blood empties into the innominate veins. Hence when the upper half of the body is raised and the jugular veins previously noted to be congested are seen to collapse, we are certain that the hydrostatic pressure in the innominate veins has been overcome. In this general sense, the collapse of the jugular veins may be utilized in the clinical diagnosis of stasis, but no exact measure can be expected for the reasons cited above, and principally because of the arterial blood-supply.

Oliver,¹ von Basch,² A. Frey,³ and Sewall⁴ have all attempted to measure the venous pressure directly, the principle of all their methods being essentially the same. Von Basch places a glass vessel open below over a superficial vein on the back of the hand and raises the pressure in the vessel until the vein collapses. The pressure exerted equals that in the vein at that moment.

Von Frey also uses a vein on the back of the hand, the arm being abducted and the hand held at the level of the right auricle, which he estimates as that of the third rib. He compresses the vein by means of a solid pelotte with a measured pressure, stroking it empty from the pelotte in a centripetal direction. In case the blood reflux is not prevented by a valve, one compresses the vein with the finger at some distance centrally from the pelotte. The vein then remains empty until the pressure in the pelotte is decreased to an amount which the blood coming from the periphery can just overcome. This pressure obviously equals the venous pressure at the point in question. Von Frey uses a metal pelotte and a kind of spring-balance arrangement which measures the pressure in grams (like Verdin's sphygmometer, p. 163). He finds the average venous pressure in health on the back of the hand to be 10-15 gm., in elderly people somewhat more, but he gives no figures in pathologic conditions. The same criticisms are to be made on the use of a spring pelotte here as in measuring the arterial pressure. (See p. 163.) The results cannot be correct, because the pressure as estimated is influenced by the caliber of the vein compressed. Sewall has improved the method somewhat by using a hollow elastic air-cushion.

The author has modified the method by using an air pelotte and a manometer. Owing to the small amounts of pressure to be measured he substitutes a manometer filled with colored water instead of mercury, the bore of which should be large enough to prevent any error from capillary action (3-4 mm.). It is difficult to observe the vein and the manometer simultaneously. A good plan is to have them both in the same line with the eye, and glance at the vein every time the water in the manometer falls a centimeter.

Von Recklinghausen⁵ has recently invented a similar method, but one which involves more complicated apparatus. He found that the pressure in a vein of the hand is practically equal to that of a blood-column the height of which equals the vertical distance between the position of the hand and the sternoclavicular joint.⁶ So that if one subtract the pressure due to the weight of this column, the pressure in the veins of the hand is practically nil. Naturally, in judging the condition of the circulation only the pressure in the veins where they enter the thorax need be considered, and this also is practically nil. The author's results do not verify these conclusions. He found the pressure often several centimeters of water above or below the value thus reckoned. He also believes that the variations in the venous pressure during the few minutes of observation depend not so much on the variations of arterial pressure as on the changes in the caliber of the smallest vessels and the veins themselves.

In stasis the venous pressure in the hand may be considerably raised, but not necessarily so, owing to the great power of dilatation and accommodation on the part of the venous walls. The author has repeatedly seen cases of high-grade cardiac stasis where the venous pressure was normal. The visible dilatation of the veins is a surer sign of stasis, but even this may be due to an increase in intrathoracic pressure (emphysema, pleurisy, pneumothorax).

⁶ This is the location of the highest point of the course of the veins leading from the hand to the heart.

MEASUREMENT OF THE CAPILLARY PRESSURE

Von Kries¹ was the first to measure the capillary pressure in man. He placed a weight on a glass plate laid on the skin, and estimated the pressure necessary to produce pallor. R. Roy and J. Graham Brown have made similar experiments on the frog's web. Von Basch² endeavored to make the measurement of the capillary pressure clinically useful. He applied an air-tight glass bell to the skin, and increased the pressure in it until pallor was produced. Von Recklinghausen³ employed the same method as in his measurements of the venous pressure, using a transparent pneumatic pelotte, and employing the blanching of the skin as an end-reaction. None of the methods produce practical results to be depended upon. The blanching of the skin appears gradually, showing that the pressure in some of the capillaries in the region under observation is greater than that in others. The pressures are so slight that the different individual resistances of the tissues play too important a part, more so even than in the measurement of the arterial pressure by Gärtner's manometric method (p. 170). The capillary pressure is also apparently much higher in some places than in others, which very materially detracts from the clinical value of such measurements.

SPHYGMOBOLOMETRY⁴

The attempt to estimate the condition of the circulation from sphygmomanometric measurements is as futile as it would be to try to calculate the horse-power of a locomotive, and even the speed of the train, from the measurement of the steam pressure in the boiler. Even the consideration of arterial pressure variations ("pulse pressure," height of the absolute sphygmograph) is of no help. A knowledge of the difference in pressure between the steam entering and the steam leaving the cylinders of an engine still leaves one in complete ignorance concerning the work of which the engine is capable.

The author, therefore, believes it would be of great service to endeavor to measure *not the blood-pressures, but the energy of the pulse-wave, and so, indirectly, the strength of the systole*. For this purpose he has constructed an instrument, the sphygmobolometer, about to be described.⁵ As in the measurement of the blood-pressure, the Riva-Rocci cuff with the author's quicksilver manometer is employed. It is necessary that as much as possible of the energy of the pulse-wave shall be transformed into measurable pulsatory movements of the mercury in the manometer. To lessen the friction, a larger tube (5 mm. bore) is used than in the measurement of the blood-pressure. This also enables a float to be placed in the longer limb of the manometer. In order to get a vigorous movement of the mercury a somewhat larger cuff should be used (8 cm. broad). The objection to the very broad ones used by von Recklinghausen in pressure measurements (13 cm.) is that they have to be applied to the arm spirally, so that the amount of surface actually in contact with the arm differs with the caliber of the arm, making it impossible to compare the results of experiments on different individuals. Only a cuff circularly applied gives a constant area of contact

⁴ See Sahli, Deut. med. Woch., April 18, 1907, No. 16 and 17. The sphygmobolometer is still in process of manufacture, so that it cannot be given to the public until later.

⁵ The name is derived from βέλος, "a throw." The author considered the names cardiodynamometer or sphygmodynamometer, but discarded them because they might easily lead to misconceptions of the essential nature of the new method.

between the skin and the cuff, and for this method of application the cuff must not be too wide, on account of the variations in the curvature of the arm. It is convenient to have the cuff connected with a small escape-tube fitted with a stop-cock, so that the pressure in the cuff may be diminished at will, and also to have a stop-cock interposed between the manometer and the bulb. The author employs a four-armed glass tube arranged as in the following diagram (Fig. 102.)

The cuff is applied to the patient's arm in the usual way, and the pressure gradually increased; at each increase of pressure communication between the bulb and the cuff is temporarily shut off, either by using a stop-cock, as above, or by pinching the tube. When a certain pressure is obtained, the mercury in the manometer will be seen to oscillate up and down. Sometimes these oscillations are visible when communication with the bulb is open, but generally they are plainer when the bulb is shut off. Some investigators have employed these oscillations to determine the pressure, *e. g.*, von Recklinghausen, in his "Trep-pencurven," and Mosso (see the third edition of his text-book, 1902, p. 128). They obviously arise from the energy of the pulse-wave, which, at a certain medium point of compression of the brachial artery, is carried through the cuff to the manometer in sufficient strength to set the quick-

Fig. 102.

silver in vibration. If the bulb be connected, the amount of air it contains, of course, materially reduces or even hides the periodic increase of pressure in the air between the pulse and the manometer. The smaller the caliber of the connecting tube and the more rigid its walls, the stronger, of course, are the pulsations. The point of pressure at which the maximum vibrations are set up in the manometer is found not to correspond to that of the maximum nor to that of the minimum arterial blood-pressure, but to lie somewhere between these, not, however, at their exact mean. This is contrary to the principle involved in Mosso's and other instruments, according to which the point at which the mercury vibrations are greatest is taken to be that of the minimum arterial pressure. As a matter of fact, experiments show that it lies between the maximum and minimum, varying with the form of the pulse-wave. In many cases it falls at no one fixed point, the mercury vibrations remaining at a maximum through a considerable range of pressure. In such cases von Recklinghausen assumes that the lowest pressure at which the maximum vibrations occur corresponds to the minimum pressure in the artery.

The author's proposed use of mercury vibrations has nothing in common with conclusions as to the state of the blood-pressure; nor is

it related to the attempts of Riva-Rocci and others to employ these vibrations in the determination of the lateral arterial pressure, a concept by no means clear to the author.

Sphygmobolometry is entirely different; it aims to determine, not the pressure, but the work performed by the pulse. The vital energy of the pulse-wave, which is transferred to the cuff, is what sets the column of mercury in vibration. If that point of compression be selected where these vibrations are at a maximum, *i. e.*, where the transformation of energy is most nearly complete, the work done by the pulse-wave can be calculated after reading off the maximum height of the mercury column. Obviously, however, such conclusions hold good only for one type of apparatus, the results being influenced by the breadth of the cuff, the volume of air-space inclosed, the quality of the rubber, etc. In his original communication¹ the author attempted to announce absolute results concerning the work done by the pulse-wave, but it must be understood that the values thus obtained were always to be multiplied by the constant of the particular instrument. If, however, instruments of the same construction are always employed, as is desirable for clinical work, this constant may be ignored, and at least relatively correct and comparable results be obtained.

One other important point must be noted. Since the maximum excursions of the mercury do not occur at the moment when the manometer shows the maximum pressure, it is obvious that a part of the pulse-wave escapes under the cuff. The author has shown that this fraction is variable, depending upon the shape of the pulse-wave.² In order, then, to secure constant conditions the wave must be prevented from escaping in part under the cuff, and as far as possible be forced to exert its energy entirely in the direction of the manometer. This is accomplished by first winding an Esmarch bandage around the arm, either at the elbow or between it and the cuff, tightly enough to obliterate the radial pulse. This device to a certain extent converts that portion of the brachial artery which extends to the lower edge of the cuff into a culdesac from the aorta (a sort of sphygmoscope).³

If, now, the energy of the pulsation be noted at this arterial stump and be measured by the excursions of the mercury, we approximately estimate the energy of the aortic pulse. The instantaneous compression of the venous trunks, caused by the pressure of the cuff, subjects not only the small veins and the arteries, but also the capillaries, to the arterial pressure, and they all pulsate with it. This naturally facilitates the completeness of the transference of energy to the mercury, since not only the small volume of the arteries, but the whole arm stump, takes part in the variations of volume. The mechanical conditions of the test are the same in every case; hence it seems proper to assume that practically constant and comparable estimates are obtained, provided, of course, that the pressure of the cuff be adjusted to secure maximum excursions. In making use of this test clinically we must evidently avoid any factor which could artificially alter the energy of the pulse-wave, *e. g.*, pain from an overtight Esmarch bandage, such as to affect the heart action. Caution, experience, and quickness in performing the experiment will, however, usually eliminate this particular factor.

¹ Deut. med. Woch., 1907, No. 16, et seq.

² Deut. Arch. f. klin. Med., 1904, vol. lxxxi.

³ See Marey, *La circulation du sang*, 1881.

It remains, therefore, merely to measure the extent of the excursions of the mercury, and to make the calculations from the data obtained. For the measurement of the excursions of the mercury, it is sufficient for purely practical clinical or demonstration purposes merely to note with the eye the highest point on the manometric scale reached by the mercury. The distance must, however, be read to fractions of a millimeter. For this purpose a scale giving fifths of a millimeter may be fastened alongside the mercury tube, and by means of a suitable telescope, the extent of the excursions be read off from a distance. For more exact purposes a graphic method of recording the results is preferable. This might be done by connecting the air-space above the mercury with a Marey tambour, and recording the excursions pneumatically on the kymographion. In this method, however, the increase due to the lever action must be calculated each time and taken into account. The author, therefore, uses a float riding directly on the mercury and carrying a writing point, which records the excursions vertically, and without magnification. At first this float had an ordinary horizontal writing arm, which, by a small hanging weight, was held pressed gently against the writing surface. The latter consisted of any kymographion preferred, or the arrangement described on p. 126

Fig. 103.—The author's sphygmobolometer.

(Fig. 49). In order to make the apparatus simpler for the practitioner, however, the author has contrived a writing surface which shall

be a permanent part of the instrument, and render it independent of any kymographion.

This consists of a piece of smoked paper, 12 cm. high, fixed in a vertical frame attached to the stand of the manometer near its base. By turning a crank the paper and its frame can be moved horizontally about 6 cm. The manometer stand is so heavy at the base that this can be done without shaking the instrument. Since we are not concerned with the time relations of the pulse, but merely with the calculation

Fig. 104.—Sphygmobologram.

Fig. 105 —Sphygmobologram.

of its energy, it is not necessary to have any clockwork for moving the paper. Figs. 104 and 105 show what neat and regular curves may be obtained by moving the recording surface by hand. To facilitate the insertion of the paper, a joint in the base of the instrument permits it to be placed in an almost horizontal position.

As the writing apparatus, for the sake of stability, must be placed as near the base of the instrument as possible, it becomes necessary to devise some means for transferring the movements of the float from

the top of the manometer tube to the bottom. For this purpose several contrivances were tested, the best proving to be the one represented in Fig. 103. A thread *ab* is attached to the arm of the float. From it hangs a thin metal wire, *bc*, bent at its end into a horizontal writing point, *cd*. This wire is guided by being passed through the glass tube, *fe*, which is fastened to the instrument. The proper amount of friction can be attained by adjusting this glass tube and a greater or less torsion of the thread.

The technic of the procedure is as follows: the cuff is attached to the upper arm and connected with the apparatus by the 4-armed glass tube. (See Fig. 102.) The brachial artery distal to the cuff is compressed by an Esmarch bandage until the radial pulse disappears. By compression of the bulb the column of mercury with its float is made to assume different heights. After the proper adjustment of the needle to the smoked paper has been made, bolometric curves are taken for the different pressures, the connection with the bulb being each time cut off. A slow movement of the paper is sufficient, because the method is concerned with the height, and not the form, of the curve. Hence a large series of pulse-waves can be recorded on one line of a paper 6 cm. wide, and by moving the smoked paper back and forth curves for the different pressure heights may be traced one below the other. (See Figs. 104 and 105.)

With such long tracings we can often note distinct Traube's waves corresponding to a periodic increase and decrease in the mercury excursions. (See Fig. 105.) Fig. 104 does not show these waves. In such instances the cardiac work, and not alone the blood-pressure, is evidently increased and decreased.

The zero pressure line is given the position of the writing point when the manometer is at rest; the height of pressure corresponding to each curve can then be easily determined by measuring in millimeters the distance from the zero line to a horizontal drawn later to intersect the points half-way between the tip and foot of the waves. Since the manometer is constructed with two limbs, this distance must be doubled. It is self-evident that this doubling only applies to measuring the mean position of the mercury, not the height of an individual wave.

For reckoning the work done by the pulse under observation we select that curve which shows the greatest excursions,¹ since at that moment the transmission of energy was most nearly complete.

In the author's first article on sphygmobolometry he deduced the following formula for the *relative* work done by the single pulse-beat:

$$(1) W = h (h + H)$$

W = work done; h = amplitude (in millimeters of mercury) of the maximum sphygmobolometric excursion; H = height (in millimeters of mercury) of the corresponding manometric pressure. In exceptional cases other values are assigned to $h + H$. (See p. 186.)

The formula gives only a *relative* estimate of the work done, in the sense that the right-hand side of the equation holds good only for the comparison of value obtained by one and the same instrument in examining different cases. To determine an absolute value, the right-

¹ If Traube's waves be present, an average excursion must be selected.

hand side of the equation must be multiplied by a constant, in the calculation of which the specific gravity of the mercury, the diameter of the manometer tube, and various other factors in the construction of the instrument are concerned. For practical clinical use the relative value is all that is required. The author has shown in his original article that the oscillations due to inertia of the mercury do not affect the correctness of the formula. The entire work performed by the pulse in one minute is obtained by multiplying the work done by a single beat by the pulse-rate.

The measurement of the pulse amplitude (height of the absolute sphygmogram, pulse pressure) differs fundamentally in principle from the measurement of the pulse energy (value of work determined sphygmobolometrically and expressed in the equation cited above). It does not depend at all upon the pulse amplitude or minimum pressure, but corresponds to the work done at the artery and expressed by the formula $W = \frac{M \times v^2}{2}$ where M = the mass of the pulse-wave which impinges upon the cuff (dependent on its form, height, and duration, as well as on the caliber of the artery), and v = the velocity of the lifting components of the wave motion—quantities which do not enter at all into the static computation of the pressure relations.

To calculate the value of W in formula (1) we select for h and H those values which correspond to the sphygmobolometric curve having the greatest amplitude of the series, because the maximum excursion of the curve naturally suggests the most perfect transmission of the pulse. At any rate, it is certain that those curves which are obtained under a *lower* manometric pressure than the curve of the maximum mercury excursion represent a lower value of work done, thus indicating an incomplete transmission of energy, and are useless for this purpose. But the maximum work, it must be noted, is under some circumstances found by selecting, not the curve with the maximum amplitude (height of excursion, h), but rather one of those immediately above it, where the decrease in h (height of excursion, amplitude) is more than compensated for by the increase in H (pressure), *e. g.*:

h	H	W
6 mm	100 mm.	$6 \times 106 = 636$
5 mm.	125 mm.	$5 \times 130 = 650$

In general, however, it will be found that the value of h falls off so quickly that the increase in H is overbalanced, so that the maximum value of W usually corresponds to the maximum value of h .

It remains to consider the clinical value of the results obtained by sphygmobolometry. It is obvious that we are computing not the entire energy of the heart, but only that fraction which acts upon the portion of the arm stump obstructed by the Esmarch bandage and corresponding to the surface of the cuff. The muscular development of the arm would naturally affect this fraction to some extent. But in healthy individuals the differences between the results are found to be so small, and in pathologic conditions of the heart so great, that the author believes it possible to consider the result found as an approximately constant fraction of the total work done by the heart in each case. Conclusions may, therefore, be drawn concerning the entire amount of cardiac work—a result impossible by any previous method.

The objection may be made that we are measuring simply the *wave energy* in the artery, and taking no account of the *current energy*. The author, however, believes such a criticism to be entirely unwarranted. For, if we measure the wave energy in a peripherally closed artery, we are really measuring the entire energy from the heart exhibited at that

point, because the current at the periphery through the capillaries, which determines the amount of the circulation, is entirely due to this wave energy. The pressure in the capillaries arises wholly from the change of kinetic wave energy into potential pressure energy. This is illustrated by a fact easily shown by the sphygmograph. If even a single pulse be lost, the minimal pressure, *i. e.*, the base of the curve, instantly falls. The arterial pulse is therefore to be conceived as a kind of peripheral heart, working not automatically, to be sure, but by its elasticity, or, to a certain extent, by its resiliency. This conception of the pulse is set forth and defended in the author's work on the absolute sphygmogram. He considers it a most important one, and exceedingly fruitful in any study of the dynamics of the circulation. It at once makes clear the significance of sphygmobolometry.

If one assume, then, that by the sphygmobolometer he measures an approximately constant fraction of the entire heart energy (its exact value depending upon the constant of the instrument), it is possible to get at least approximately relative values for the active circulation.

Let W = the work done in the systole; P = the normal mean pressure in the brachial artery or the aorta; P^1 = the corresponding pressure in a pathologic case; S = the volume of the normal systole; S^1 = the volume of the abnormal systole. Then approximately:¹

$$\begin{aligned} W &= SP \quad \therefore S = \frac{W}{P} \\ \text{and} \quad W^1 &= S^1 P^1 \quad \therefore S^1 = \frac{W^1}{P^1} \\ &\quad \therefore \frac{S^1}{S} = \frac{W^1 P}{W P^1}. \end{aligned}$$

Let $\frac{W}{n} = w$ represent that fraction of the entire work of the heart measured at the brachial artery by the sphygmobolometer in the normal case,

$$\text{and} \quad \frac{W^1}{n} = w^1 \text{ in the abnormal case;}$$

$$\text{then} \quad \frac{S^1}{S} = \frac{W^1}{W} \cdot \frac{P}{P^1} = \frac{w^1 n}{w n} \cdot \frac{P}{P^1} = \frac{P}{w} \cdot \frac{w^1}{P^1}$$

i. e., the systolic volumes vary directly as the amounts of work done (measured by the sphygmobolometer), and inversely as the corresponding mean arterial pressure.

If, now, the fraction $\frac{P}{w}$ be established once for all for normal cases, and be designated by N (normal), then:

$$(2) \quad \frac{S^1}{S} = N \frac{w^1}{P^1};$$

i. e., the ratio of the pathologic systole to a normal systole is equal to the product of the value N (including the constant of the instrument) by the ratio of the sphygmobolometric energy to the mean pressure in the pathologic case.

Of course, in a valvular insufficiency, only the utilized portion

¹ Sahli, Deut. med. Woch., 1907, No. 16.

of the systole is included in this computation because the unutilized portion of the systole, the regurgitation, does not appear in the sphygmobologram.

It is obvious that the foregoing conclusions will not hold unless the energy measured at the brachial artery represents a constant fraction of the entire heart energy (*i. e.*, N is a constant). It is, however, probable that such is the case, owing to the conditions of the procedure: (1) the brachial artery is converted into a blind appendage of the aorta; (2) it is, therefore, strongly distended; (3) the veins are cut off by the pressure in the cuff, and the capillaries therefore pulsate with the artery. Hence the conditions are in a great measure independent of the variations in caliber and contraction of the brachial artery, and, so far as this is possible in biologic questions, investigations on the work done by a single artery may also be used for comparative conclusions concerning the entire work done by the heart. This is all the more the case, since the influence of the state of contraction of the pulsating artery will be in a measure eliminated because of the relaxation of the arterial wall caused by the pressure of the cuff, and the best possible transmission of the pulse will thereby be obtained.

It must be emphasized that we do not measure the actual systolic volume in cubic centimeters. To do this we should be obliged to know the absolute value of the normal systole (S). We are able merely to measure the ratio between the volumes in circulation in the two cases. In other words, to decide whether in a given case the systolic volume is subnormal, normal, or above normal, and whether it remains constant during the period of observation, or increases, or decreases. These are the questions which sphygmobolometry can answer, and they are certainly most important questions for the practising physician. Time and clinical experience must, however, prove whether this new method of the author's is practically useful. It may at any rate be asserted that the technic is simple and requires but little time, not nearly so much as that needed for sphygmography and the graphic measurement of the maximum and minimum pressures, as determined by Janeway, Masing, Strassburger, von Recklinghausen, and Sahli. The first task must be to determine the normal figures for the cardiac energy exhibited in the arm by normal individuals of different heights and weights, with which to compare the results in pathologic cases. In passing it may be said that the effect of drugs on the circulation may be determined much more certainly by sphygmobolometry than by any other hydraulic method. The author will also here repeat what he mentioned in 1901 at the Berlin Congress for Internal Medicine, that an improvement of the circulation often results in no increase of arterial pressure, but that, paradoxically, the pressure is sometimes lowered. Therefore, as he has shown in his article on the absolute sphygmogram,¹ no conclusions concerning the condition of the circulation can be drawn from the maximum blood-pressure or even from the height of the absolute sphygmogram or the pulse pressure. But the sphygmobolometer curve distinctly shows any change in the circulation. See the curve showing the effect of digitalis, reproduced in the author's original article.

Sphygmobolometry cannot be replaced by the sphygmograph, although it is true in a way that it is the pulse energy that sets the sphyg-

¹ Deut. Arch. f. klin. Med. 1904, vol. lxxxi.

mograph in motion. For measuring the energy, sphygmobolometry has the following advantages over sphygmography: (1) the pulse of the whole extremity is being investigated in the neighborhood of the aorta, and not merely the pulse of one small artery; (2) the energy is transmitted permanently to the registering apparatus and is, therefore, independent of accidents of application and the caliber of the individual artery; (3) a simple formula is deducible instead of an exceedingly complicated empirical law.

It should be added that this procedure corresponds to the old-fashioned method of feeling the pulse, which sought to estimate the force of the pulse-wave rather than the height of the blood-pressure. This method has been entirely neglected of late on account of the disproportionate modern insistence on the static conception of the circulation, and yet this method of feeling the pulse ("energetisches Pulsfühlen") is perhaps the most practically useful one, since it focuses the attention on the work done by the pulse-wave without regard to the blood-pressure. (See p. 118 for the author's argument in its favor.) It *appreciates* the pulse energy, which the more exact methods of bolometry records and measures. It is obvious that the mere observation of the extent of the mercury excursions may be employed in diagnosis to show the size or, according to Marey, the strength¹ of the pulse. For clinical demonstrations the float should carry a paper flag to make its movements more easily visible at a distance. The author has already shown (p. 141) that in the ordinary sphygmogram the volume of the pulse has a very indefinite significance; but in the sphygmobologram it always represents a fixed amount of energy. In the interpretation of the results we must evidently beware of confusing the idea of "performances" (work accomplished) with "capacity for performances." (functional capacity).

This method measures, not the amount of work which the heart is capable of performing under increased demand, but the amount which it actually performs at a given moment, *e. g.*, the performance of the heart and the size of the circulation in a healthy individual at rest may appear very small; and yet this does not preclude such a heart's capacity for a very much greater task under the stimulus of vigorous muscular work. Hence in a given case the functional examination may have to be supplemented in this respect by noting the alteration of the sphygmobologram after making an increased demand of the heart, *e. g.*, lifting a weight with the free arm. With a heart capable potentially the work (*W*) (measured sphygmobolometrically) increases materially; with serious cardiac insufficiency, on the contrary, this work does not increase and may even decrease.

¹ In judging the cardiac energy, not only the extent of the mercury excursions, but also the overpressure, must be taken into account; and for judging the systolic volume the mean arterial pressure (see formula 1 (p. 185), and 2 (p. 187)). The latter formula shows that a high blood-pressure must be associated with a higher volume for the pulse energy than a low pressure if a normal systole is to be assumed. This also applies to the author's "energetic feeling" of the pulse.

VISIBLE PHENOMENA OF MOTION IN THE VESSELS

CAPILLARY PULSE

Under normal conditions the blood flows smoothly and without a pulse in the capillaries, either because the resistance in the smallest arteries completely deprives the pulse-wave of its energy at this point, or because, as von Frey and Krehl believe, the pulse-wave is completely reflected centripetally. (See p. 133 et seq.) Under some conditions however, the pulse is transmitted to the capillaries, and becomes evident to inspection in the form of a pulsating reddening and blanching of the parts in question. Whatever facilitates the entrance of a pulse-wave into the capillary areas, or whatever renders the flow into the veins difficult, will, of course, favor the production of a capillary pulse. The larger the pulse-wave and the more it approaches the type of *pulsus celer*, the more the conditions for a capillary pulse are favored. A capillary pulse is sometimes observed over hyperemic, and especially over inflammatory, areas, *e. g.*, over felons. Very frequently the patient himself appreciates the increased pulsation in inflammatory parts as a throbbing pain. The capillary pulse, due to a *pulsus celer*, especially in aortic insufficiency, is of far greater interest. This is a very common, although not a constant, sign in this valvular lesion. It is perhaps best appreciated by observing the alternate blushing and pallor at the finger-nail. Sometimes enough pressure upon the anterior part of the nail-bed to blanch the nail brings out a margin between red and white which oscillates with systole. Care should be taken not to allow the influence of the examiner's own pulse to cause a rhythmic pressure. The capillary pulse in aortic insufficiency may be very frequently appreciated at other places which are characterized by their redness, *e. g.*, ears, lips, cheeks.

[A clean glass slide lightly pressed upon the extended lower lip will sometimes bring out the capillary pulse when it cannot be appreciated at the finger-nail. Another useful device is to rub a spot upon the forehead until it is hyperemic and then look for an alternation of redness and pallor.—Ed.]

Contrary to many statements, a capillary pulse is by no means pathognomonic of aortic insufficiency. Any condition which will produce a *pulsus celer* (exophthalmic goiter, fever, chlorosis) will be apt to show a capillary pulse. If the circulation be very active, it may sometimes be observed even in health. Although not absolutely pathognomonic of aortic insufficiency, it is so common in this lesion and so rare in other conditions that the sign really possesses considerable diagnostic significance. The sign becomes most distinct during the stage of compensation. The existence of an actual stenosis complicating the insufficiency may interfere with the appearance of a capillary pulse. The retinal vessels will show a visible pulsation with the ophthalmoscope when a capillary pulse is visible elsewhere.

THE EFFECT OF RESPIRATION UPON THE VEINS

The respiratory variations in the interior of the thorax, as is well known, influence the venous circulation very distinctly. Inspiration

hastens, expiration retards, the flow of venous blood. The influence is ordinarily not evident in the visible veins with superficial breathing,

Fig. 106.—Venous engorgement during forced expiration—case of phthisis (New York City Hospital).

Fig. 107.—Distention of jugular vein, accentuated during inspiration; a case of leukemia with enlarged mediastinal glands (Dr. Joseph Collins, New York City Hospital).

but forced breathing will produce an inspiratory diminution and expiratory increase in the size of these veins, and if they be already dis-

tended by congestion, the change will become still more evident. Both conditions are usually present in dyspnea.

Variations in intrathoracic pressure become more distinct during coughing or other exertions which raise the abdominal pressure. The intrathoracic pressure then becomes markedly positive, and the veins, especially the cervical veins, become decidedly distended during the coughing paroxysm or effort of straining, while during the next deep inspiration they suddenly collapse again. When this periodic congestion is frequently repeated, especially in patients who suffer from chronic cough, a permanent dilatation of the veins, particularly of the jugular, may result, so that with coughing or straining the whole lower portion of the neck becomes swollen. The "bulbs" of the jugular veins may appear as large swellings, either just inside or outside of the insertion of the sternocleidomastoid (Fig. 106). The bulging of the supraclavicular fossæ during a cough, therefore, should not always be attributed to a distention of the lung apices (p. 107.)

In very rare cases the reverse condition is observed, *i. e.*, a distention of the veins during inspiration and a collapsing or a diminution during expiration; this always suggests that during inspiration some mechanical compression of the veins exists within the chest. This phenomenon has been described as a sign of fibrous mediastinitis, like the *pulsus paradoxus*. (See p. 142.) It may, however, depend upon the effect of inspiratory pressure or traction upon the large veins leading to the heart, due to interference with the mobility of the thoracic contents (pericarditis, pleuritis, mediastinal tumors, see Fig. 107).

THE VENOUS PULSE

The arterial pulse-wave usually disappears in the capillaries, *i. e.*, it is reflected centripetally (see p. 190 et seq.), so that the blood no longer pulsates, but flows uniformly in the venous radicles. Nevertheless under both physiologic and pathologic conditions characteristic pulsations synchronous with cardiac action are frequently observed in the greater veins lying near the chest (almost exclusively in the jugular veins).

There are several pathologic varieties of this pulsation. One type of venous pulse must, however, be considered absolutely physiologic, because it is constantly observed after exposing the vein in healthy animals, and because individuals who show it are perfectly normal. That this venous pulse is not observed in everybody is due to the fact that in some people the jugular veins are not visible or are seen only with considerable difficulty. Conversely, this physiologic venous pulse can naturally be seen with especial readiness in people whose veins have become more noticeably distended by congestion.

If the valves at the upper end of the jugular bulb close properly, the venous pulse will be chiefly apparent in the bulb (bulbous pulse). The closure of the bulbous valves prevents only the actual regurgitation of blood as it occurs in the venous pulse of tricuspid insufficiency, and not its wave-like motion coming from the heart. The latter, in closing the bulb valves, produces above them, from the backing up, a positive wave of exactly the same shape. Consequently, by carefully watching a bulbous pulse, we can appreciate that the veins do pulsate above the bulb valves, although less than below. Very

frequently, however, as the result of congestion, the venous valves become insufficient, so that the pulse may be seen just as distinctly in the upper part and in the small branches of the jugular vein as over the bulb itself.

When the distended veins become distinctly visible (in venous pulse the external jugular veins are chiefly concerned), it is generally a simple matter to distinguish between their pulsation and that of the neighboring arteries. The pulsation of some deeply seated vein (internal jugular) which cannot be directly observed is much more difficult to determine. But even then the venous pulse can be easily recognized, particularly by the large area of pulsation involved, corresponding to the large size of the vein, by the slow, undulating transmission of the beat, and by the very moderate amount of power to be felt in the pulsation, depending upon the slight amount of tension of the venous contents. If the pulsation be transmitted from an artery to a vein, compression of the vein will not affect the pulsation peripheral to the point of compression, and sometimes the resulting congestion will make the pulsation even more distinct. An accentuation of the pulsation from compression otherwise occurs only with the very rare penetrating venous pulse. (See p. 197.) Under some circumstances the venous pulse may also be appreciated at the liver as the liver venous pulse.

A reliable diagnostic valuation of the venous pulse and a sure differentiation of its varieties can only be obtained by comparing its phase and rhythm with the

Fig. 108.—Graphic representation of the apex-beat, carotid pulse, jugular pulse, and liver pulse compared with the radial pulse (after Mackenzie).

phase of the heart action and the rhythm of the arterial pulse. Since this determination by mere inspection and palpation is very difficult, it is best to make use of the graphic method, whereby both pulses can be recorded.

Fig. 109.—Physiologic (negative, presystolic) venous pulse (Riegel).

An easier procedure has been advocated by Volhard.¹ By means of small glass funnels, one of which is placed over the pulsating vein or over the liver area and the other over the carotid, the pulses are transmitted through hollow tubes to two manometers filled with differently colored fluids and placed side by side. It

¹ Congress for Internal Medicine, 1902.

is then very easy to ascertain whether the two water columns rise alternately or simultaneously. On account of their inertia the two columns of water should be of the same height. The connecting tubes, however, need not be of equal lengths, because the air-waves are propagated through them with the velocity of sound.

Fig. 110.—Positive centrifugal (systolic) venous pulse in tricuspid insufficiency (Riegel).

This procedure sometimes gives very definite results, but sometimes fails on account of the difficulty of fully isolating the venous pulse from the movement imparted to the vein by the carotid. The same difficulty is met in the graphic method (see below).

Fig. 111.—Diagrammatic representation of the course of the pressure during one heart cycle in the auricle, ventricle, and aorta (after von Frey).

For the graphic method we usually select the external and internal jugular veins and the radial artery. The apparatus is described on p. 126 et seq. Simple glass funnels, or the metal receivers used by Mackenzie (Fig. 129), are placed on the artery and on the vein. On the latter, a spot as free as possible from the trans-

mitted arterial movement, should be selected. The two curves are recorded on the same paper (Mackenzie). In spite of the fact that the radial pulse is delayed in relation to the apex-beat by the length of closure time, and by the time necessary for transmission of the pulse to the artery, it is usually easy to decide whether the venous pulse is synchronous or alternate, with the ventricular systole. If any difficulty is experienced, it is advantageous, as Mackenzie has shown (see p. 152), to compare the radial pulse with the apex-beat, carotid pulse, and venous pulse in succession, as in Fig. 108 (Mackenzie).

The jugular venous pulse is generally more distinct if the patient be recumbent. We cannot always interpret every peculiarity of such a venous pulse-curve, because the arterial pulse often inevitably interferes with the venous pulse, and sometimes secondary peaks are caused by reflected waves, which cannot be properly explained, and which may lead to erroneous and arbitrary conclusions.

Until recently two varieties of the venous pulse were sharply differentiated as follows: *a*, Fig. 109, which represents the so-called "physiologic venous pulse," "negative venous pulse," "systolic venous collapse," "venous undulations," "negative centrifugal venous pulse," or "presystolic venous pulse"; and *b*, Fig. 110, which represents the "pathologic," "positive centrifugal," or "systolic" venous pulse. This sharp distinction, and with it a part of the nomenclature, must to-day, however, be abandoned, as is evident from the following discussion of the origin and essential nature of the venous pulse.

The venous pulse is plainly due to rhythmic variations in the pressure of the venous blood. Except in one instance, to be discussed later as the "penetrating venous pulse" (see p. 197), the rhythmic movement of the arterial blood has been lost before it reaches the veins, so that the variations of pressure in the ordinary forms of the venous pulse must be due to impulses starting from the right auricle and transmitted against the blood-current. The study of the variations of pressure in the right auricle, under physiologic and pathologic conditions, must, therefore, furnish the key to the explanations of the venous pulse. Von Frey's¹ exact analysis of the variations of pressure in the auricle, ventricle, and aorta is represented in the following diagram:

The classification of the venous pulse attempted here is supported by the following discussion.

AURICULAR VENOUS PULSE

The pressure-curve of the normal auricle must evidently represent, with but insignificant variations, the normal venous pulse-curve. (Compare Fig. 109, the physiologic venous pulse, with the upper curve in Fig. 111.) The obliquely ascending line with which the curve begins (Fig. 111) is the expression of the filling of the right heart by the continuous influx of blood from the veins, and is modified by the increased intrathoracic pressure caused by the increase in the size of the heart (auxocardia), which diminishes the suction and tends to produce stasis in the veins. The steep rise following it is the effect of the systole of the right auricle by which, since the pressure works equally forward and backward from the auricle, the pressure in the veins is increased in spite of the emptying of the auricle into the right ventricle. It is by no means necessary to assume an actual regurgitation of the blood into the veins. Physiologists assume that this is prevented by the circular contraction at the venous orifices coinciding with or even before the auricular systole. The damming of the venous stream by the increased pressure in the auricle, plus this contraction, produces a stasis wave in the veins. The apex of the venous curve, and that of the auricular curve, correspond then to the systole of the auricle (presystolic). During the diastole of the auricle, corresponding to systole of the ventricle (Fig. 111), the auricular pressure falls and the curve descends rapidly to *x*. This steep auricular descent, the most strongly marked characteristic of the so-called normal venous pulse, is apparently also due in part to the negative pressure in the thoracic cavity, caused by the lessening of the volume of the heart during systole (meiocardia) which sucks the venous blood toward the heart. For, as the figure shows, the fall of the venous pulse-curve coincides with the aortic pulse, i. e., the period of meiocardia. From the point *x* the pressure in the auricle and veins rises again, because the relaxed auricle is again being filled. In the first part of this period the ventricle is still contracting. At the moment when ventricular diastole begins (line 4 in Fig. 111) the auriculoventricular valves open, and the pressure naturally sinks again in the auricle and veins, the curve falling to *y*. This completes one heart cycle and one so-called normal or physiologic venous pulse. Since the summit corresponds to the systole of the auricle, the terms *presystolic* and *auricular*

¹ Die Untersuchung des Pulses, Berlin, 1892.

venous pulse are both justifiable, as is also the term *physiologic*, in so far as this pulse is to be observed under quite normal conditions, provided the veins are plainly visible. The expression "negative" pulse should be abandoned, for it puts too great emphasis on the depression of the auricular curve (x , Fig. 111), which is called a negative wave, as if any such negative wave or fall were possible without a preceding positive wave or rise. This explanation of the venous pulse is in no way affected if one assume an actual regurgitation of blood into the veins instead of mere stasis on account of the hindrance to the blood-stream, for either cause would give rise to a positive centrifugal venous wave. Mackenzie's designation of the second apex (between x and y , Fig. 111; c' , Fig. 109), as the *ventricular* wave is not justifiable, because this summit is not the expression of the ventricular contractions as the first summit is of the auricular contraction, but occurs only after the greater portion of the ventricular contraction is finished. The fact that the depression y is due to the relaxation of the ventricle is not sufficient to justify designating the summit B as the ventricular wave. Under pathologic conditions, to be sure, a true ventricular wave may be developed from this second summit, as we shall see below, and this is evidently responsible for Mackenzie's incorrect terminology.

VENTRICULAR VENOUS PULSE WITHOUT TRICUSPID INSUFFICIENCY

The normal venous pulse may be altered by either one of two conditions: (1) Paralysis of the auricle, often caused in heart disease, as Mackenzie has shown, by the distention of the walls from stasis; and (2) tricuspid insufficiency.

In the former the auricular wave, which is characteristic of the physiologic venous pulse, obviously disappears more and more completely. The factors which then cause alterations of pressure in the auricle and veins are: (1) The gradual passive increase of pressure, resulting from the augmented filling of auricle and ventricle together with the increasing intrathoracic pressure (auxocardia); (2) the contraction of the right ventricle, causing stasis in the veins and right auricle; and (3) the diastole of the right ventricle, suddenly unloading the auricle. The negative intrathoracic pressure (meiocardia), dependent upon the systolic emptying of the heart, tends to suck the blood from the veins, to be sure, and so opposes the

Fig. 112.—Diagram showing the transformation of the auricular venous pulse (I) by gradual disappearance of the auricular wave into the ventricular venous pulse (III) caused by increasing paralysis of the auricle without tricuspid insufficiency.

stasis due to ventricular contraction, but its effect upon the veins is less direct and rapid, so that it cannot prevent the stasis. Neither can the increased intrathoracic pressure (auxocardia) overbalance the stronger suction of the ventricular diastole. The two important factors, then, are: (1) The systole of the right ventricle, causing stasis; and (2) the diastole of the right ventricle, unloading the auricle and veins. The resulting venous pulse will be synchronous with ventricular systole, and may, therefore, be called a *ventricular systolic venous pulse*. Its form is shown in Fig. 90, although there it is due to the regurgitation of the blood in tricuspid insufficiency, and not to paralysis of the auricle. (See Fig. 110.) It is obvious that different degrees of insufficiency in the muscle-wall of the auricle will give rise to differing transitional forms between the physio-

logic auricular pulse and the purely ventricular pulse of paralysis of the auricle (Fig. 112), and that, as the wave A (Fig. 111) grows smaller the wave B will be shifted backward into the point corresponding to that of ventricular systole.

VENTRICULAR VENOUS PULSE RESULTING FROM TRICUSPID INSUFFICIENCY

In this case the regurgitation of the blood during the systole of the right ventricle causes a venous pulse of ventricular systolic type. Unless the auricle has lost its ability to contract, the physiologic, presystolic, or auricular pulse will also show more or less plainly. The more the distention of the auricle paralyzes its wall, the less prominent the auricular wave appears. In Fig. 110 it is still visible as an anacrotic elevation. An increase of the tricuspid insufficiency, accentuating the steepness of the ventricular wave's ascending limb, anticipates its summit, and so conceals the auricular wave. A comparison of such a venous pulse with the carotid pulse (Fig. 110) shows that the former occurs slightly before the latter. This may

be due to the fact that the first portion of the ascending limb of the venous pulse-curve is still due in part to the auricular contraction, but it can also be explained by the fact that the regurgitation toward the veins coincides with the beginning of the ventricular contraction, while the aortic valves do not open until the pressure has augmented, i. e., at the end of the so-called "closure time," a term, to be sure, only partially applicable in tricuspid insufficiency. On account of its greater energy this variety of venous pulse is the one which most readily gives rise to an audible tone at the bulbous valves of the jugular vein. (See Auscultation of the Veins)

TRANSITION FORMS BETWEEN THE AURICULAR AND THE VENTRICULAR VENOUS PULSE; THE CAROTID WAVE

Such forms are due most frequently to the varying degrees of completeness of the auricular contraction (see above), but angular venous pulse-waves are also sometimes due to the influence of the carotid pulse, manifesting itself either in a dislocation of the whole venous curve or as a peculiar extra elevation in the curve (Fig. 113).

Fig. 113.—Physiologic (so-called auricular) venous pulse with an extra elevation (c) arising from the carotid pulse (after Mackenzie). As the figure shows, c is synchronous with the carotid pulse; v is Mackenzie's so-called ventricular wave (p. 196).

The latter may be seen more plainly on deep inspiration. The recognition of such variations is essential to the proper understanding of many modifications of the venous pulse, although they cannot be given a simple name.

POSITIVE CENTRIPETAL OR PENETRATING VENOUS PULSE

This rare type of venous pulse is produced when the arterial wave possesses sufficient force to penetrate the capillaries and transmit a pulsating motion to the venous radicles. It is illustrated in the experiments of Claude Bernard, who, by stimulation of the chorda tympani, dilated the vessels of the submaxillary gland sufficiently to cause the arterial pulse to be transmitted to the veins. The phenomenon evidently depends upon conditions similar to those producing the capillary pulse and has been found chiefly in aortic insufficiency. Quincke, however, believes that a capillary pulse does not always accompany a penetrating venous pulse, but, on the contrary, that we may be unable to appreciate the pulse-wave in the capillaries because it is spread over too great an area, whereas the decrease of the sectional area of the streams in the venous radicles, under favorable pressure conditions, may cause the pulse to become visible again. This type of venous pulse occurs especially with an arterial pulsus celer; perhaps also in pronounced hyperemia of the tissues with excessive dilatation of the capillaries. It usually appears, not in the jugular vein, but in the small veins of the extremities. Compression will obliterate the pulse in the central portion, but not in the peripheral part of the vein.

DIASTOLIC VENOUS COLLAPSE (FRIEDREICH)

This very rare phenomenon was described by Friedreich in connection with systolic retraction from pericardial adhesions. (See later Palpation and Inspection of the Precordia.) The diastolic bulging of the chest-wall produces a diastolic suction within the thorax, and this is supposed to cause the veins to collapse. It is,

so to speak, the reverse of the physiologic auricular venous pulse. In the latter the vein is flattened during systole; in the phenomenon described by Friedreich the collapse occurs during diastole. It is, therefore, somewhat similar to the ventricular venous pulse. According to Brauer's theory of the diastolic thoracic projection, the diastolic venous collapse would be considered as a direct result of an accentuated diastole.

Fig. 114.—Friedreich's diastolic venous collapse (after Mackenzie).

The diastolic venous collapse may be differentiated from the ventricular venous pulse by the visible thoracic diastolic projection, and chiefly, according to Mackenzie, by the broad plateaus in the curve between the diastolic depressions (Fig. 114).

THE LIVER PULSE

A pulse palpable at the liver is generally the expression of a venous pulse demonstrable also at the jugular vein. But an *arterial liver pulse* may occur with a pronounced pulsus celer of aortic insufficiency and in inflammatory conditions of the liver. The *liver pulse* can be appreciated best by palpating the liver, as far as possible to the right of the median line, so as to avoid confusion with an epigastric pulsation or with an aortic pulsation, which is sometimes transmitted to the liver. (See later section upon Palpation and Inspection of the Precordia.) To avoid such errors, it is especially important to be convinced that the pulsation is really expansile, i. e., that the volume of the liver increases intermittently. This can generally be best accomplished by firmly grasping the edge of the liver, or by employing bimanual palpation, one hand behind pressing the liver forward against the other hand in front. This is usually easy on account of the enlargement of the organ.

For the graphic record of the liver pulse, Mackenzie's "liver receiver" (p. 129) is pressed closely around the edge of the organ and the side opening then closed with the finger. The pulse is then recorded in the same way as the venous pulse at the jugular vein.

It was formerly held that a plainly expansile liver pulse was always systolic (ventricular), and, if an arterial pulse were excluded, it was a reliable diagnostic sign of tricuspid insufficiency. But Volhard has shown that in congestion of the liver, a presystolic (auricular) pulse is not infrequent. The author's theory of the venous pulse in general would also militate against even the systolic liver pulse being conclusive evidence of tricuspid insufficiency. (See p. 195.)

Mackenzie reports that in congestion of the liver he has practically never failed to demonstrate a liver pulse graphically, and that it is a much more constant symptom than a jugular venous pulse. This may be easily explained by the fact that the stasis is much more marked at the liver, because at the neck it is combated by the force of gravity, tending to empty the veins.

In opposition to Volhard, Mackenzie considers a presystolic liver pulse a sign characteristic of tricuspid stenosis.

Mackenzie has shown that epigastric pulsations may shove the liver outward during systole corresponding to the negative character (the systolic retraction) of the ordinary epigastric pulsation assumed by him. This movement of the liver will give rise to a curve like that of a presystolic auricular venous pulse, except that the wave B (Fig. 111) will be lacking. In such cases the differential diagnosis may be made by means of palpation.

An *arterial liver pulse*, as has been said, sometimes occurs in aortic insufficiency as a result of the pulsus celer and in inflammation of the liver. It can be differentiated from the *venous liver pulse* only by a careful consideration of all other conditions.

REMARKS ON THE MODERN UTILIZATION OF THE VENOUS PULSE-CURVES FOR THE ANALYSIS OF DISTURBANCES OF THE RHYTHM OF THE HEART-ACTION

In the recent literature on the rhythm of the heart action and its disturbances, many attempts have been made to deduce, from the graphic records of the venous pulse, far-reaching conclusions concerning the nature of the action of the right heart, and so to obtain data for the interpretation of any anomalies of the heart action present. The author considers these attempts proper and praiseworthy, but lacking in sufficient searching criticism on the part of those presenting them. The latter have not taken into account the enormous difficulty, especially in irregular pulses, caused by reflected waves. Just as in the arterial pulse-wave, the primary wave is often confused by all kinds of secondary reflected waves, of whose diagnostic significance we know but little (see p. 133) on account of their involved etiology. The same difficulty occurs with the venous curve, and the detection and interpretation of secondary waves in the latter is even more difficult. For, on account of (1) the low pressure; (2) the marked variations in pressure with different positions of the body caused by gravity; and (3) the slow rate of propagation of the wave, whose movement may often be followed with the eye, the retardation of the reflected waves, and consequently their position in the curve, are much more variable than in the arterial pulse-curve. The carotid pulse may also interfere with and influence the venous curve in varying ways, depending on its own form and on the place at which it acts upon the vein. The influence of respiration has also been too little considered. In irregular heart action, where, to be sure, these analyses of the venous pulse play an important part, the difficulties of such analyses become often immeasurable, just on account of the irregularity and the persistent variation with each heart action. (See p. 152 et seq.). The positiveness with which such problematic interpretations of highly irregular venous pulse-curves have been presented in recent writings is very astonishing, and evidently comparable to the phase in the history of the arterial sphygmogram, now past, when from it, too, were drawn similar far too extensive conclusions.

PERCUSSION

PERCUSSION IN GENERAL: INSTRUMENTS

The examination of the human body by means of percussion (or striking) plays an especially important rôle in the modern diagnostic methods of internal medicine. The condition of the organ or organs underlying the spot percussed is determined or, at least, inferred from the sound produced. We accredit the discovery of this method to the Vienna physician Auenbrugger, for in the year 1761 a description of it appeared in his work, *Inventum Novum*. However, the method was not generally employed until after Corvisart, Napoleon I.'s, physician, translated Auenbrugger's work into the French (1808) and appended extensive observations of his own as commentaries. Manifold modifications, theoretic confirmations, and improvements in interpretation were then added to the method by a great number of authors, of whom we need only mention Piorry, the inventor of the pleximeter; Barry, the inventor of the percussion hammer; Wintrich, Skoda, Traube, and A. Geigel. Hence, although the method is already more than a century old, it really only became the common property of physicians during the second half of the nineteenth century. To-day percussion and auscultation have become the corner-stone of diagnosis. The student must learn both at the very beginning of his clinical experience.

There are countless methods of percussion. Originally only *imme-*

diate (direct) percussion was employed, *i. e.*, the striking of the surface of the body directly with the tips of the fingers. But where the body-covering is soft, such a method will elicit only indistinct and impure sounds, and therefore to-day we use almost exclusively *mediate (indirect) percussion*, *i. e.*, either a finger of the other hand or a specially constructed instrument—the pleximeter—is interposed between the striking finger and the surface of the body. The theory of this arrangement has been recently worked out by R. Geigel.¹ The “plexor” is a small hammer furnished with a rubber tip. It may be substituted for the striking finger.

In *mediate (indirect) percussion* we may use either: (1) Finger-finger percussion; (2) finger-pleximeter percussion; or (3) plexor-pleximeter percussion.

Individual taste or habit will generally determine a preference for one of these methods. There are certain differences and advantages in each, although we may be skilful or awkward with any one of them. The finger-finger percussion is the most difficult to learn; but in many cases it furnishes more accurate results than the pleximeter percussion, because the inherent note of the pleximeter is liable to confuse the percussion tone. It has been held by many authors, particularly by Ebstein, that, consciously or unconsciously, the sense of touch in the finger-finger percussion aids the sense of hearing (palpation-percussion).² But the chief advantage is that the physician is independent of instruments, which may be readily forgotten, mislaid, or broken. The finger pleximeter, and especially the plexor-pleximeter, percussion methods are much easier to learn, and greater differences of sound may be more readily demonstrated and appreciated by a larger circle of listeners; nevertheless, a percussion-note which is loud enough to be heard at considerable distance is suitable only for certain cases (see below). A physician should be familiar with all three methods, and he should be able to control his own results by applying first one and then the other, for despite the utmost care and great skill, the subjective har-

¹ Deut. Arch. f. klin. Med., 1907, vol. lxxxviii, p. 598.

² This conclusion has recently been combated by Moritz. He maintains that if all aid from the sense of hearing be excluded (by closing the ears and working in a noisy room) the sense of touch alone will lead to either negative or erroneous conclusions. He is, therefore, inclined to consider that the sensation of a greater or less resistance appreciated by the touch, which indisputably accompanies the acoustic perception on percussion, is in reality only a secondary sensation. It is to be considered as suggested by the sensations, appreciated by the hearing, or as the result of an unconscious process of induction. In other words, one reasons from a loud percussion-note to a less resistance, from a faint note to a greater resistance. The author shares these misgivings. He is also inclined in general to condemn the combination of two kinds of sense impressions in one method of examination. If he wishes to palpate, he palpates, and uses no accompanying percussion. If he is percussing, he considers it best to concentrate his entire attention on the sounds heard, which often are appreciated exactly and correctly judged only with difficulty. In any case, this mixing of sense impressions contains an instinctive, almost an unconscious, element, which offers great difficulties for scientific analysis and for teaching purposes. The beginner cannot easily be shown how to direct his attention in percussion toward two sensations at once, both of them, moreover, difficult to appreciate and to judge. A certain mastery of the procedure, gained by long experience, is essential. Ebstein especially recommends his palpation percussion for the determination of the total size of the heart (corresponding to the deep cardiac dulness). But it is difficult for the author to understand how such deep-lying boundaries can be appreciated by touch. He would consider that the palpatory sensations in that case would be determined rather by the conditions of resistance of the thorax in the neighborhood of the heart, taking into account the sternum.

acter of the method often in difficult cases leaves a doubt in the mind of the examiner. A plexor and pleximeter are of some advantage in the employment of the plexor-pleximeter method (p. 205), although we can substitute a bit of wood, a pencil, or the like for the plexor, and a coin or another bit of wood for the pleximeter.

In certain cases (*e. g.*, for determining slight pathologic dulness in the chest or abdomen and for differentiating the deep cardiac dulness) *immediate (direct) percussion* is to be recommended as a control. The examiner thus avoids too strong pressure of the pleximeter or of the finger of the left hand, a very common fault with beginners. *Immediate (direct) percussion* is made by striking with the tip of the middle finger or the tips of the four fingers and thumb of the right hand arranged like a pyramid.¹ In percussing the lung apices beneath the clavicles the bone serves as a pleximeter, and the middle finger of the right hand as the plexor.

Laennec combined percussion and auscultation by listening with the stethoscope at a spot near to that being percussed ("percussion auscultation," "percussion transsonance," see the use of this principle in the "stick-pleximeter" percussion, p. 205). Runeberg has recently called attention again to this procedure, recommending its use in general in determining the boundaries of an organ. He places the stethoscope over the spot at which the organ in question lies nearest the thoracic wall. He then percusses over the organ lightly, if it lie deeply or merely strokes the skin with the finger if the organ lie superficially. The finger is then gradually moved away from the stethoscope. As long as it is over the organ, a distinct sound is heard, transmitted through the organ and the stethoscope apparently directly to the ear, but as soon as the boundary of the organ is passed, the sound disappears or loses its direct character. Runeberg claims that in this way he is able to map out both superficial and deep organs, and to distinguish not only, as in ordinary percussion, the boundaries between air-containing and solid organs, but also those between two air-containing or two solid organs (*e. g.*, stomach and colon, colon and small intestine, heart and liver, liver and gall-bladder, heart and a neighboring pleural exudate, air in the thorax and lungs or stomach). The author has not been able to confirm these results. He considers the method reliable only for the determination of the boundary between a solid and an air-containing organ, and then only when both lie superficially and when percussion, not stroking with the finger, is used, because if stroking be employed, the sound produced by friction with the skin is too prominent. The deeper the organ lies, the more subjective and unreliable he finds the method. He has failed entirely to determine by it the boundary between organs not differing in their air-content. He is, therefore, not convinced that it is better than ordinary percussion. Smith and others have announced very peculiar results in the diagnosis of heart conditions by their so-called "friction method," *i. e.*, listening with the "phonendoscope" (see section on Auscultation) to the sounds produced by friction against the skin. These investigations were undertaken chiefly in the interest of the total abstinence movement, and the results cannot be confirmed by objective observers. The author considers the method absolutely worthless and misleading.

Only continued practical experience can teach the technic of percussion, and but few rules are worth stating.

The percussion stroke should be made perpendicular to the surface of the part percussed.

*The So-called "Orthopercussion."*²—Goldscheider has recently recommended that in the percussion of the deep cardiac dulness the stroke should be made perpendicular to the frontal plane and not to the surface of the body, even when the sides of the thorax are being percussed. He claims that in this way "sagittal sound-waves" are dispersed through the thorax, and that, therefore, the true size of the heart is projected upon the thoracic wall, uninfluenced, as in perpendicular percussion, by the convexity of the surface of the thorax (comparable to Moritz's orthodiagraphy with Roentgen rays). The author finds two objections to this theory. In the first place, a body of such complicated form and structure as the thorax with its contents cannot possibly vibrate exclusively in one linear direction, or even

¹ Zeit. f. klin. Med., vol. xlii.

² Deut. med. Woch., 1907 (two numbers) and Cong. f. inn. Med., 1907.

predominantly so, as Goldscheider more cautiously puts it in the last-cited publication. The vibrations must be considered as curves of three dimensions, whose greatest axis depends not only on the direction of the stroke, but also on that of the axis of maximum elasticity. A second and much more important objection is the fact, that in percussing toward the sides of the thorax the direction of the blow would become more and more nearly tangential to the surface, and, therefore, a continually increasing part of the force would be ineffective in producing vibrations. In other words, the force of the percussion blow would be a variable not a constant. This method would, therefore, be approximately accurate, according to the author's experience, only for parts of the thorax lying nearly in the frontal plane, *e. g.*, in general for a heart of normal size. It would be difficult to make such a method apply to a heart whose apex-beat is felt in the axillary line. This is the cause of the dullness always elicited by percussion over a sharp convexity of the bowed ribs, for the reason that a larger proportion of percussion stroke impinges in the direction of the axis of the ribs and is lost in their arch.

In finger percussion the nail of the percussing finger should be cut short, and the blow should be struck with the pulp of the last phalanx in such a manner that not only the direction of the stroke but also the axis of the last phalanx is perpendicular to the pleximeter and to the surface of the body part percussed. A perpendicular stroke is essential for producing a good, uniform note. It is especially difficult for the beginner unless he be a piano player. Both in plexor and in finger percussion the stroke should be light, short, and elastic, produced by merely bending the wrist-joint, at the same time avoiding any cramped position of the hand or fingers. Percussion should in general be light (weak) (see later). Many beginners misinterpret the distinction between light and strong percussion, a mistake which should be avoided. (See p. 215.) The so-called *strong* or *deep percussion* should also in most cases be quite delicate, so that the note cannot be heard at any great distance.

The pleximeter, *i. e.*, the finger to be struck, should be placed with its palmar side upon and in close contact with the surface of the body and parallel to the border to be differentiated. Only light pressure should be employed, because strong pressure even with light (superficial) percussion will cause a diffuse vibration of the body on account of the larger area affected, and so simulate the effect of a stronger (deep) percussion. (See p. 213.)

Instead of the usual pleximeter, a bit of firm, gray erasing rubber, cut about 1 cm. wide, 1 cm. thick, and 4 cm. long, will answer the purpose well if the physician be not skilled in finger percussion. Like the finger, such a pleximeter has practically no intrinsic curve; it can be easily bent to conform to the curves of the chest-wall, and it can be struck with the hard end of the hammer or with the finger.

In percussing a child's body very much less force must be used than for the adult. (See Deep and Superficial Dullness.)

QUALITY OF THE PERCUSSION

RESONANT AND DULL, TYMPANITIC AND NON-TYMPANITIC, PERCUSSION-NOTES¹

Even a layman, percussing different regions of the body surface, is able to recognize that one part furnishes a resonant, another part a dull, note. An accurate differentiation between resonant and dull notes, or between different grades of resonance, is the groundwork of percussion.

¹ For the theory of the origin of the different tones, see p 206.

A typically resonant note can be obtained by percussing over the lung; a typical flat note, by percussing over great muscle masses, *e. g.*, the thigh. Experience has taught us that resonant notes are produced over organs containing air; dull notes over organs without air, quite irrespective of whether they are solid or filled with fluid. Therefore percussion, on the one hand, defines the boundaries of the different organs; and, on the other hand, by changes in the resonance of the note, determines any increase or decrease of air contained in the organ. The less air, other conditions remaining the same, the duller the note. The resonance of the note also varies decidedly with the deep diameter of the air-containing organ, *i. e.*, the diameter in the direction of the percussion stroke. The thicker the layer of air, the more resonant the note. (See the section on Deep Dulness, p. 213.) The influence of the tension of the wall surrounding the air cavity upon the resonance of the note will be mentioned later.

We apply the terms *resonant* and *dulled* to the percussion-notes, using these words as they are ordinarily employed. *Clear* is often used as synonymous with *resonant*, and *muffled* as synonymous with *dulled*. But these terms should be abandoned, since in common usage *clear* usually implies a high, and *muffled* a low, tone, so that beginners may easily be led into misconceptions by their use. The word *dulled* as opposed to *resonant* is, on the contrary, unmistakable. When a resonant note is modified by a dulled note, we speak of the presence of *dulness*; a note which is neither very resonant nor very dull is called *relatively dulled*; an absolutely dull note, on the contrary, *absolutely dulled* or *flat*. The terms *absolute* and *relative dulness* have a corresponding signification.

In defining the quality of a percussion-note many modern authors employ the terms short and long as synonymous with dull and resonant. Theoretically, this is not quite correct, because the latter expressions characterize the intensity of the note; whereas short and long refer, on the contrary, to its duration, and the latter must depend upon the size and elasticity of the vibrating mass. The length of a musical instrument's note is of very essential importance to the tone and value of the instrument. A musical ear can, in fact, easily differentiate this peculiarity of duration in a percussion-note. However, in the relations of percussion which concern us a resonant note is almost always long and a dull note short. The exceptions to this rule have no special diagnostic importance, so that the expressions short and long may as well be eliminated.

There are countless gradations in quality between the two extremes resonant and flat or clear and muffled, the differences depending upon the amplitude of the note vibrations. There are, however, other very important differences of quality which we must heed and which depend upon variation in the form and number of vibrations. The most important of the latter is the distinction between *tympanitic* and *non-tympanitic* resonant notes. This distinction is illustrated by comparing in a healthy person the note obtained over the lung with that obtained over the air-containing abdominal viscera. The pulmonary note is resonant, but not tympanitic. The note over the stomach and intestines is resonant, and also tympanitic. Both tympanitic and non-tympanitic notes are really noises in the purely physical sense; but in tympanitic notes the vibrations are sufficiently periodic (*i. e.*, tuneful) for the ear to be able to compare their number with the number of vibrations of other sounds; in short, to be able to recognize a certain pitch. This

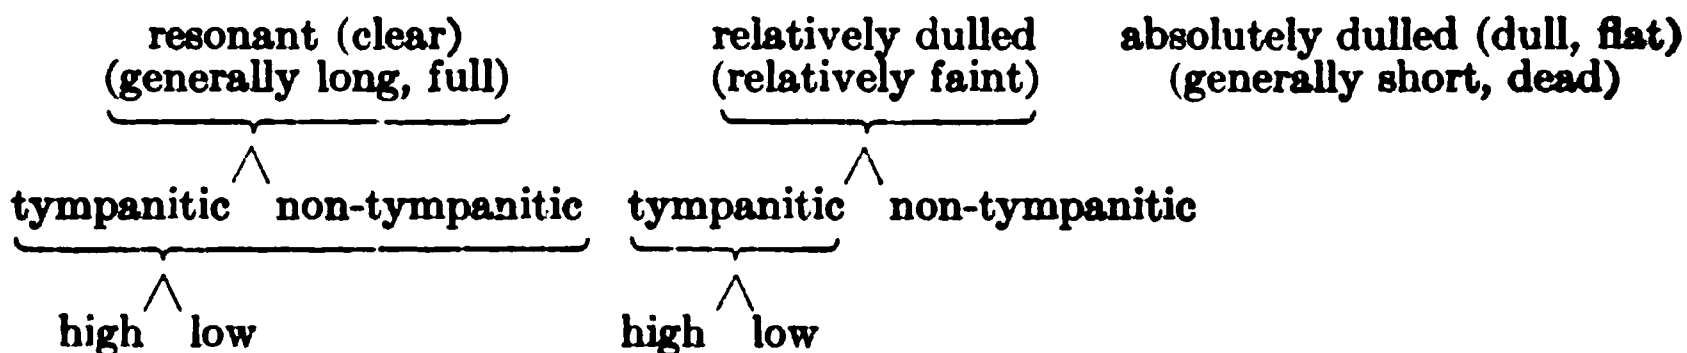

theoretic differentiation between tympanitic and non-tympanitic notes will not make the matter much clearer to a beginner; but in a practical demonstration a musical ear will very readily appreciate the distinction between the resonant but non-tympanitic lung note and the true tympanitic note of the bowels. No sharply defined boundary really exists between tympanitic and non-tympanitic notes.

Experience teaches us that a non-tympanitic note will be transformed into a tympanitic note when the tension of the air within the organ diminishes, *i. e.*, when its wall is relaxed; and the converse is also true, that with an increase in tension a tympanitic will be transformed into a non-tympanitic note. If we inflate a pig's bladder while at the same time we percuss over it, we shall notice that up to a certain point of distention the note is tympanitic, but with further inflation non-tympanitic. During the transformation of a non-tympanitic into a tympanitic note its intensity or sonority increases; in other words, the note first becomes hyperresonant before it becomes tympanitic.

The essential characteristic of a tympanitic note, as has been said, is a certain definite pitch, so that naturally we can distinguish a low tympanitic from a high tympanitic note, and gradations between the two. Different tone heights (pitch) cannot be distinguished easily in non-tympanitic notes. The pitch of a percussion-note depends upon various factors, above all, upon the tension of the wall inclosing the air-space and upon the size of the latter.

It is self-evident that more than one of the qualities discussed may characterize the same percussion-note. Thus, *e. g.*, we may speak of a relatively dulled high tympanitic note, or of a resonant low tympanitic note.

The following scheme of the tone qualities described above may be useful:

There are two other specific tone qualities which must be mentioned, *viz.*, *metallic resonance* and the "*cracked-pot*" sound or *cracked-pot resonance*.

METALLIC RESONANCE¹

Metallic resonance means a peculiar quality of the percussion-note, which is best characterized by its name. It can be imitated by percussing one's own distended cheeks with a plexor and pleximeter.

Its metallic character depends upon an individual metallic overtone of a definite pitch, which can be appreciated sometimes during the entire duration, sometimes, however, only at the end of the sound. In the latter case we speak of it as a *metallic after-resonance*.

The latter is probably due to a faint metallic resonance at first

¹ For the newer theory of the origin of metallic resonance see p. 206.

obscured by the ordinary percussion-note and audible only at the end of it.

We are especially indebted to Wintrich for the older experiments upon metallic resonance. He showed that this sound arises only when large air-spaces are percussed. These may be closed or open; but if open, the orifice must be relatively narrow, *i. e.*, in proportion to the cross-section of the cavity. The inner surface of the cavity-wall must be comparatively smooth, because, according to Wintrich, metallic resonance depends essentially upon the reflection of the air-waves which percussion sets into vibration within the cavity and their interference with one another. This produces the high, inharmonious overtones responsible for the metallic character of the sound. The thinner the walls, the easier the metallic character can be appreciated. For a criticism of Wintrich's theory see p. 206.

If the walls of the cavity be yielding (flexible), metallic resonance will not result unless they are under a certain moderate tension. Again, a cavity must be of a certain size to produce metallic resonance; according to Wintrich, its greatest diameter must be at least 6 cm. Smaller cavities very rarely furnish metallic resonance.

The metallic resonance noted in percussing the normal human body is in most cases so faint that it can be appreciated only when the ear is very near or is connected with the percussed area by means of a stethoscope (auscultatory percussion). The easiest way to appreciate metallic resonance is by means of the "stick-pleximeter" method (Heubner). In this method we percuss with the handle of the plexor upon a bit of stick, a coin, or some other firm object placed upon the body, and at the same time auscultate with the stethoscope in the immediate neighborhood. In case a coin is used, care must be taken to dull its own metallic resonance. By the reverberation of the high overtones in the "stick-pleximeter" method the resulting shrill noise seems particularly to favor the production of a metallic resonance. (See also, however, p. 208.) Metallic resonance may accompany non-tympanitic as well as tympanitic notes; but in the former case it can be appreciated only by the aid of the stick-pleximeter method of percussion.

Metallic resonance can be elicited sometimes over physiologic cavities, *e. g.*, the stomach and intestines; sometimes over pathologic collections of air, *e. g.*, lung cavities, pneumothorax, pneumopericardium.

If the cavity contain fluid as well as air, change of the patient's position may alter the pitch of the metallic resonance. This is because its pitch depends partly upon the greatest diameter of the air cavity, which would be altered by the shifting of the relative positions of the fluid and the air.

CRACKED-POT RESONANCE

(Brutt de Pot Fele; Noise of the Chink of Coins)

This peculiar clanging or rattling percussion noise can be simulated by filling the hand with coins, shutting it tight enough to allow only a slight space for the coins to move, and then shaking the hand; or, in another way, by clasping the hands together firmly, leaving a slight air-space between, and then striking the back of one hand against the knee.

The force of the blow will expel some air through the narrow chink between the hands. Another method is to strike a hollow rubber ball with a narrow opening vigorously enough to expel some air with each stroke. Such experiments, as well as the conditions in the chest which are responsible for the phenomenon, make it probable that the cracked-pot sound observed in man is a stenotic murmur following the primary tympanitic tone; the percussion blows expel air quickly through a narrow, slit-like opening. (See p. 210 for its diagnostic significance; p. 208 for the theory of its origin.)

A THEORETIC DISCUSSION OF THE PERCUSSION-NOTE, BASED UPON RECENT EXPERIMENTS

The foregoing analysis of the different qualities of the percussion-note is based partly on ordinary acoustic laws, partly on the older and rather meager experiments (of Skoda, Wintrich, Zamminer, Gerhardt, Sr., and Eichhorst), which analyzed the tones by means of a resonator, and partly on an exact comparative analysis of the tones actually heard on percussion. How important and reliable the last (subjective) method is is proved by the fact that its results have been, in almost every instance, confirmed by the recent objective experiments about to be described. We owe these experiments to A. Geigel and Theo. Selling. The latter, with Edelbaum and Scripture at F. Müller's instigation, undertook the investigation of the percussion-note by means of the newest physical apparatus.

For the comprehension of what follows it must be understood that, according to Helmholtz, there is no sharp distinction between a *noise* and a *tone*. Each can be resolved into simpler tones. Practically the boundary between them lies at the point where the ear fails to distinguish any one pitch on account of the interference of the partial tones. This distinction obviously depends to a great extent on the natural power of the individual ear. If several keys of the piano be struck together at random, the result generally gives the impression of a mere noise, on account of the difficulty of distinguishing the individual tones, although in this case the "noise" is obviously composed of musical tones, and is not very different from certain "harmonies" of modern orchestration which are tolerated by the present generation. Similarly in physical diagnosis the lack of a sharp distinction between a noise and a tone is observed in studying the transition between tympanitic and non-tympanitic percussion-notes. From both, however, the pure "tones" of Helmholtz are to be distinguished by their purely sinusoidal vibrations.

In the percussion of air-containing organs the organ and the air contained in it obviously vibrate together as a whole; so that the old discussion as to whether the resonant note of air-containing organs was produced by vibrations of the air or of the surrounding tissue was wholly futile. Vibrations of the lung substance without synchronous vibrations of the air-content are certainly as inconceivable as are vibrations of the air-content without the participation of the lung substance. R. Geigel's comparison of the percussed lung to percussed foam is, therefore, entirely pertinent.

Selling¹ first determined, by means of both Einthoven's galvanometer and the phonograph, that a resonant (lung) tone is distinguished from a dull (lung) tone by the greater amplitude of the vibrations. This corresponded exactly to the older view. He also established by both methods the more interesting fact that a resonant tone lasts longer than a dull one, thus confirming our early theory that in general a parallel exists between resonant and dull and full and dead tones. Such a parallel is, of course, not invalidated by the fact that the terms "full" and shallow express something fundamentally different from the terms "resonant" and "dull," namely, the duration of the vibration, which depends, other things being equal, upon the mass and the elasticity of the vibrating body.

Selling also investigated the pitch of the percussion-note. By means of the resonator he proved the pulmonary tone to be a very complex one, made up of many partial tones, among which the deep notes predominate. The range of pitch of the resonant, non-tympanitic pulmonary tone is from low F to high C. In healthy adults it goes down to about low A; in children to middle F; in patients with emphy-

¹ Deut. Arch. f. klin. Med., vol. xc, parts 1 and 2, p. 163. See also F. Müller, Zeit. f. ärztl. Fortbildung, 1906, parts 15 and 17.

sema to low F. The normal resonant pulmonary tone is therefore preëminently deep. The dull tone, on the contrary, is higher in pitch, since the deeper tones are subdued through the decreasing capability of the lung for vibration. All this supports the proposition (p. 203) to set aside the terms clear for resonant and muffled for dull, since one usually means by clear a high, by muffled a low, tone.

This determination of the predominance of deep notes agrees with the fact, pointed out by Selling, that the vocal (tactile) fremitus is felt only when the patient pitches his voice low. In women there is often no appreciable fremitus, since their high voices are not in harmony with the deep lung tone. In children, however, it is more perceptible than in women, since, although their voices are higher, so is also their normal pulmonary tone, on account of the smaller volume of the lungs.

According to Selling, the determination of the highest pitch of the notes composing the pulmonary tone is less important, for this depends more on the intrinsic tones of the hammer and pleximeter or of the percussing and percussed fingers. This agrees with the fact that a dull note over the lung generally seems higher, because the deep pulmonary tones are fainter, while the higher notes of the pleximeter are unchanged. Since the dull pulmonary tone is essentially a weakened tone, and since light percussion weakens the tone, it follows that in light percussion we tend to get a higher pitch, *i. e.*, one more influenced by the tones of the percussion apparatus. This is a point of some importance in the discussion of the relative merits of strong and light percussion for the determination of deep dullness (p. 215).

Selling also found the tympanitic character of a tone to be due to the greater preponderance of one fundamental tone and the partial tones near it in the scale. This has so far been determined by the resonator alone, but not through the curve of the string galvanometer.

R. Geigel's experiments chiefly refer to the determination of the conditions causing the tympanitic note and the metallic resonance, with some other phenomena of interest in physical diagnosis connected with the latter. He believes their explanation lies in the correct application of principles laid down several decades ago by Helmholtz. The differences between the ordinary resonant, the tympanitic note, and metallic resonance are, he maintains, caused by differences in conditions determining the number of overtones accompanying the fundamental. These conditions were explained by Helmholtz. He discovered that the more the vibrating body vibrates in its dependent parts, no less than as a whole, the more overtones will arise. If a stretched string be set in vibration by drawing it to one side at its middle point and releasing it, it vibrates primarily as a whole, so that the fundamental note is clearly heard. Every part of the string passes the position of equilibrium almost synchronously and in the same direction. Still, even here the movement transmitted from the initial movement of the string is not instantaneously communicated to all parts of the string, so that nodes are formed dividing the string into a certain number of equal parts, which vibrate independently in alternating directions and more rapidly than the string as a whole. These independent secondary vibrations give rise to overtones. According to Helmholtz, the number of overtones depends on the way in which the initial movement is given to the vibrating body. The more the transmission to all parts of the string is disturbed, the more overtones are formed. For instance, if instead of the string being slowly drawn to one side and released, it be struck sharply with a hammer, the movement given to it becomes more complex and the overtones are increased. The shorter the stroke, the less completely and quickly is the movement transmitted to the rest of the string; the more nodes and the more overtones are, therefore, formed. This is particularly true when the hammer is made of hard material. In that case the string gives a clanging sound. This is the reason the hammers in a pianoforte are cushioned, since the duration of contact between hammer and string is thus increased. The clanging sound of the uncushioned hammer is caused by the large number of high overtones, for in general the higher overtones are not in harmony with the fundamental tones, *i. e.*, their rates of vibration do not stand in any simple ratio to the rate of vibration of the fundamental tone. The clanging of a mass of metal when struck owes its peculiar metallic quality to such high overtones. The same causes that produce the overtones in a vibrating string produce them also in a vibrating membrane or a vibrating volume of fluid or air. Abundant overtones are caused by variations in the rapidity of vibration occurring very frequently throughout the vibrating body.

Air-containing organs, such as the lung and intestine, fall, when percussed, into permanent vibrations the same as do solid bodies and the gaseous content of hollow chambers. The percussed masses may vibrate as a whole (ground tone) or with superficial nodes (overtones). Geigel has shown what conditions determine (by

giving rise to overtones) simple, clear, tympanitic, metallic resonance. The tympanitic note is the simplest sound elicited by percussion. Here the fundamental tone and the lower overtones in harmony with it are so predominant that the ear can recognize a distinct pitch, and the vibrating mass vibrates as a whole or with only a few nodes. The non-tympanitic note contains, on the contrary, many overtones, obscuring the fundamental note. The transition from tympanitic to the non-tympanitic notes may be obtained by percussing a pig's bladder inflated with air. Up to a certain point of distention the note is tympanitic; after that, non-tympanitic (p. 204). Geigel attributes the tympanitic character of the note, in the first instance, to the fact that the comparatively relaxed and yielding wall permits a sufficiently longer duration of the contact between the wall and the percussing instrument for the movement to be transmitted to the whole bladder, so that it vibrates primarily as a whole, as does a string struck with a cushioned hammer. If, on the contrary, the bladder be markedly distended, contact is so short as to give rise to a circumscribed undulation of the surface before the movement has reached the more distant parts of the bladder. In this case, so many different portions of the bladder vibrate independently that a vast number of overtones are produced and the sound is a mere noise. Up to a certain grade, however, the ear can distinguish pitch in mere noises, so that even a non-tympanitic note may be recognized as having a deeper pitch in some cases than in others.

Geigel attributes metallic resonance to a preponderance of very high inharmonious overtones. As a rule, this naturally occurs in non-tympanitic notes. The author cannot agree with Geigel in his assumption that the existence of metallic resonance necessarily excludes the presence of a tympanitic note and vice versa. There might be conditions where now the fundamental note, now the high overtones, predominate without detriment to the musical character of the fundamental note by a large number of lower overtones, *i. e.*, the metallic resonance need not originate in a non-tympanitic note. That a fundamental tone and metallic overtones do not absolutely exclude each other is shown in amphoric breathing, the conditions of which are the same as those of metallic resonance, and in which a deep fundamental tone as well as high overtones can be recognized. The fact that the degree of tension of the air in the percussed cavity is a determining factor in producing metallic resonance agrees with Geigel's theory, as may be shown by puncturing the chest-wall in pneumothorax. Metallic resonance occurs only over rather large air-containing cavities apparently because: (1) Small ones vibrate too easily as a whole; and (2) larger ones containing many small cavities (the lungs) possess too little elasticity to produce enough nodes. The significance of Heubner's stick-pleximeter percussion for eliciting metallic resonance lies, according to Geigel, in the fact that the blow is made exceedingly short, so that many high overtones result. The older explanation may also, however, be true (p. 205), for the high note caused by the blow on the stick reverberating from the cavity may contribute to the metallic character of the resulting sound. Geigel's explanation of metallic resonance is more satisfactory than Wintrich's, because it explains the origin of the characteristic high discordant overtones, whereas the latter's theory of reflection and interference fails to explain why the whole series of overtones which would produce the ordinary pulmonary tone does not occur.

Scant attention has been paid to the physical basis of "cracked-pot" resonance (p. 206). Though obviously related to metallic resonance, its nature and its causation are essentially different. It may possibly be due to high discordant overtones not sufficiently isolated to produce the metallic resonance. The expulsion of air through a narrow opening plays a part in causing it. Apparently the edges of the opening are set in vibration, and an opportunity is thus given for the production of high overtones by interference.

TOPOGRAPHIC PERCUSSION

PERCUSSION CHARTS; SUPERFICIAL AND DEEP DULNESS OF ORGANS; LIGHT AND STRONG PERCUSSION; SITUATION OF THE ORGANS; ORIENTATION POINTS AND LINES

Topographic percussion signifies the determination of the boundaries of the organs of the body by means of percussion. By this method we attempt to project the boundaries of the organs upon the body surface, and to represent these relations conveniently in the history sheets, the

*Horizontal
mamillary
line*

Fig. 115.—Chart of anterior body-half.

borders are sketched upon a chart of the human body, with a skeleton drawn inside. Figs. 115, 116, and 117 show such percussion charts. Perhaps they would be still more convenient if they were double the size. Since every man's skeleton is not of the same shape, it is advisable to represent by some mark, *e. g.*, a cross, the boundary points which are

quite normal in their relation to the skeleton. (See Fig. 123.) Such a chart is rarely absolutely accurate.

The possibility of employing topographic bounding of organs which partly overlap one another depends upon the fact that some are filled

with air and some are solid. A solid organ gives a dull, a hollow organ a resonant, note. In rare cases the qualitative variations of the resonant note can be utilized for defining the boundaries. For example, we can differentiate the resonant but non-tympanic note of the lung, or the low tympanic note of the stomach, from the high tympanic note of the intestine. But naturally the differences are often very slight, and the qualities of the resonant notes merge into one another without sharp boundaries, so that the distinction is by no means easy.

The first essential for successful topographic percussion is to localize the percussion stroke. Where the boundaries to be defined are superficial, that is, where they lie directly under the body-wall, the lightest possible percussion will evidently succeed best. As soon as we percuss more vigorously, the blow will be transmitted too far, producing mixed tone phenomena. *To appreciate superficial boundaries, therefore, it is a good general rule that we should percuss as lightly as possible, and a good criterion of the desired strength is to evoke practically no note over the dulled areas.*¹ Then the same strength of percussion will produce a very plain resonant note just as soon as we encroach upon the edge of an organ containing air, *e. g.*, in percussing the lower lung boundary over the liver.

Special attention should be directed to another point in determining the superficial boundaries. The skilled observer instinctively heeds it; but the beginner, despite his best endeavor to percuss lightly, disregards

¹This is the method of percussion which Goldscheider has recently named "*threshold percussion*," but curiously enough he recommends it for percussing the deep cardiac dulness and not for superficial dulness. (See p. 216.)

Fig. 116.—Chart of left lateral body-half.

it, and so fails in a correct differentiation. *It is not only necessary to percuss lightly, but the pleximeter or the finger of the left hand serving this purpose should be brought into very light but perfect contact with the surface of the body.* The mere weight of the finger is sufficient. Firm pressure of the pleximeter (or finger) will simulate the effect of strong percussion, because the impact of the percussion will penetrate much more intensely, further into the depths and to the sides, and so prevent a linear localisa-

Posterior median line.

Fig. 117.—Chart of posterior body-half.

tion of the boundary between two superficial organs, the one containing air and the other solid.

The whole secret of success in percussing superficial boundaries depends on these two principles—light percussion and light contact.

The rationale of such light contact between pleximeter and body surface is founded upon the following considerations: Discontinuity of the thoracic vibrations, essential to localize the percussion impact properly, can only be secured in this

way. The light application of the pleximeter materially shortens in duration the influence of the percussion stroke in that the percussion impact is transmitted to the thorax for the shortest possible time, namely, during the moment when the percussion blow itself causes a more intimate contact between the pleximeter or pleximeter finger and the chest-wall. There is no such transmission before this brief moment, because the contact is not sufficiently intimate, nor after it, because the rebound of the pleximeter again interrupts the contact. This abbreviation, interrupting the impact action, prevents any considerable transmission of the mechanical impression along the body surface, and therefore secures a sharper lateral localization. It further eliminates a considerable part of the percussion power and so accomplishes the weakest possible percussion.

Disregard of this essential factor, light contact, robs supposedly light percussion of the greater part of its advantages and explains the poor percussion results obtained by many observers who lack confidence in this method. On the other hand, the author has noticed that even beginners learn to percuss superficial boundaries correctly in a very short time, ever since he has laid great stress on this point in his teaching. Even for comparative percussion (see p. 258) this method has decided advantages in the determination of very slight superficial dulness, *e. g.*, small consolidations of the lung.

This light percussion for estimating superficial boundaries is called briefly *superficial percussion*; and the dulness mapped out by the method is called *superficial dulness*. It is the easiest for the beginner to differentiate. Its position and extent generally correspond quite accurately to the position of the part of the organ adjacent to the body-wall.

So much for the determination of superficial boundaries; in many cases, however, the boundaries of organs which we wish to differentiate lie in the deeper parts, *e. g.*, most of the heart is covered by the lungs, and yet it is very desirable to estimate its size by percussion. Naturally this is a much more difficult differentiation than that of superficial boundaries. The blow must, of course, penetrate the tissues to the depths of the organ in question, in order to obtain tone differences sufficient to determine, at least approximately, the position of the deep-lying boundaries. The intensity of the note will depend upon the thickness of the layer of air that we percuss. The more air-containing tissue that is set in vibration, the louder (more resonant) the note. If *a b* (Fig. 118) represent a cross-section through the anterior wall of the thorax, and *c d* one through the heart, then by moderately strong percussion in the direction of the arrows *e* and *f* the shaded elliptic areas will be set in vibration.¹ Weil has named such an area "the acoustic sphere of action of the percussion blow."

For reasons which follow later the author considers this expression unfortunate and prefers to substitute for it "sphere of the blow" or "area of the blow." The elastic vibration transmitted into the deep tissues within the area of the percussion blow is responsible for the acoustic phenomena in percussion. At a certain depth, the inner boundary of the blow, the resistance of the tissues reduces these vibrations to zero. Then an elastic recoil reflects the vibrations to the body surface and so produces the sound. The phenomenon resembles striking a violin string, with the difference that the percussion blow vibrates the tissue in three dimensions of space, whereas the violin string vibrates but in two. The elasticity of the parts produces not only to-and-fro vibrations, but also contributes periodic secondary elastic vibrations, just as with the violin string, and thus conditions essential to the production of tone phenomena result. According to this conception, the movement impulse

¹ It is probably unnecessary to explain that the shapes of these areas, represented in the figure as perfectly regular ellipsoids, are purely hypothetical, for naturally the percussion stroke is not transmitted the same distance into the solid heart as into the lungs which contain air and are elastic. The former is dislocated by the stroke practically in toto, whereas the lungs are elastically compressed. The general proposition, however, is in no way altered by this peculiarity.

for the percussion-note proceeds from the primary deformity of the tissues within the sphere of action of the blow; and the strength of this impulse is estimated by the formula: the energy, $E = \frac{\text{mass} \times (\text{velocity})^2}{2}$. Hence, it is evident without

further discussion that the intensity of the resulting note which depends upon this energy within the sphere of the blow, other things being equal, is proportional to the mass or volume, mainly the depth of tissue affected by the blow. Practically, this is limited to the air-containing tissue, because the solid organs destroy the note. Hence, in percussing over an air-containing organ toward the border of an adjoining solid organ the intensity of the note will diminish as soon as the sphere of the percussion blow reaches to the solid organ.

Percussion at *e* (Fig. 118) will elicit a resonant note, whereas at *f* (when the sphere of the blow reaches the heart) a so-called "relative" though not an "absolute" dulness will be appreciated. The nearer the blow approaches the solid organ, the duller the note, until at the point where the solid organ reaches the surface the note becomes absolutely dull or flat—*superficial dulness*. More deeply situated organs can under some circumstances be outlined by the position of a relative dulness. The percussion adjusted to bring out this type of dulness is called *deep percussion* and the resulting dulness *deep dulness*. The pleximeter or the pleximeter finger must be applied lightly to determine even deep dulness, but so that the contact with the body surface is perfect.

Fig. 118.—The acoustic spheres of the blow in deep percussion—origin of the deep dulness.

The effect of this precaution, which, by the way, is not generally appreciated, has already been discussed (p. 211). The latter vibrations of the percussion stroke in comparison with those directed deeply are diminished and the area of the blow forms a narrower ellipse and so naturally defines the boundaries of deep organs more exactly.

In addition to applying the pleximeter lightly the examiner must avoid too strong a percussion blow, so as to prevent lateral transmission as much as possible, because strong percussion prevents any exact localization.

For superficial percussion the percussion stroke should be as light as feasible, so as to include as small a sphere of the blow as possible; but for deep percussion the strength of the stroke and the contact of the pleximeter should be adjusted so that the sphere of the blow will just include the deep-lying organs (as is shown in Fig. 118). To accomplish such a result deep percussion need in reality be only a little stronger than superficial percussion. The not uncommon designation of deep percussion as "strong percussion" is unfortunate. The finer results even of deep percussion cannot be demonstrated to a circle of listeners at any distance from the examiner. Percussion strong enough to accomplish the latter purpose produces, for the most part, incorrect results and is at best only available for the demonstration of gross relations.

The exact strength of percussion and the approximate firmness of contact of the pleximeter are very difficult for a beginner to learn and require long practice. A helpful plan is so to adjust the strength of percussion and the degree of contact of the pleximeter as to *produce the most intense dulness and to bring out the differences between the notes as plainly as possible.*

The above conception, viz.: that the deep dulness of organs depends only upon the volume of the air-containing parts in the region of the sphere of the blow were first advanced by Weil, and according to the author's belief represents not only decided progress in our theoretic knowledge, but also a firm basis for the rules of percussion given above and practised successfully for years.

It was formerly believed that the solid organs themselves not only produced a slight tone, but were even capable of partially dulling the loud resonant tone of the neighboring air-containing organs. According to this hypothesis the deep dulness depended upon the dulling influence of the solid organs in the neighborhood of those filled with air. Weil¹ has experimentally proved that such dulling influence does not exist.

An attempt has been made to discredit this conception of deep percussion, and although based upon physically incorrect premises, the arguments, nevertheless, merit a brief mention. It has been claimed that the vibration produced by even the lightest percussion penetrates deeply into the body, so that the above-assumed sphere of action of the percussion blow is incorrect. This claim was based largely upon the following experiments: Light percussion upon the anterior surface of the thorax sets into vibration a sensitive flame attached to its posterior surface; further, with light percussion a great difference in the resulting note depends upon whether the individual examined lies upon a hard support, upon a mattress, or upon an air-cushion; and finally percussing a man standing against a door decidedly alters the note. Arguments opposing the theory of the limited sphere of action of the blow which are in part founded on these long-recognized facts are, so it seems to the author, based upon premises which are inaccurate from the standpoint of physics. The experiments prove merely that even when percussion is light, *sound vibrations may* penetrate the entire body and may cause phenomena of resonance on the opposite side to that percussed, *i. e.*, they may be influenced by resonance, and so influence the result. This is quite as comprehensible as the conduction of the percussion-note to the examiner's ear. However, perhaps a part of each experiment shows that in percussing upon the anterior surface of the bony thorax the stroke is conducted through the skeleton and around the lungs to the back. But none of the experiments show anything about the behavior of the *primary action of the percussion stroke in the interior of the air-containing organs*, although this must essentially influence the percussion-note. These critics have not carefully analyzed the process of percussing deep-lying organs. The author's presentation emphasizes the importance of defining the *primary* sphere of the percussion blow over air-containing organs as that part of these organs, generally ellipsoidal, into which the mechanical action of the blow penetrates before it is destroyed by friction. The relatively light percussion recommended by the author does not penetrate very far on account of the softness of the affected organs, which absorbs the shock of the impact as soft earth lessens the mechanical effect of a bullet or a cushion the impact of a billiard ball. This direct or primary action of the percussion blow itself must not be confused with the tone vibrations. The latter, as already emphasized, are more the consequences of the primary impact, depend upon the elastic recoil of the tissues

¹ A. Weil, Handbuch und Atlas der topographischen Percussion, Leipsic, 1877. Pleural effusions only apparently produce a dulling influence, the Rauchfuss or Grocco triangle, upon the healthy side of the thorax. (See p. 265 et seq.) For unless the examiner is very careful to minimize the strength of his percussion stroke upon the healthy side, some part of the exudation adjacent to the vertebral column will necessarily be included in the sphere of the blow. When even the lightest possible percussion elicits such a triangle of dulness, it is because the effusion of the affected side crowds the lung upon the healthy side and diminishes its air-content.

directly affected by the primary stroke; and can, therefore, naturally be transmitted through the entire body of the person examined to its posterior surface and even through the air of the room to the observer's ear, since, as a result of the slight excursions of the parts vibrated incident to their production, tone vibrations penetrate almost all bodies readily and to a great distance. This, however, is quite a different type of movement from the primary action of the blow. The conditions may perhaps be made clearer to the reader by comparing the primary action of the blow in the region of the so-called sphere of action of the percussion stroke to the primary excursions of a tense violin string struck by a hammer. As soon as the hammer rebounds, the string vibrates to and fro, producing the tone vibrations of the surrounding air and of the sounding board. Or we can directly compare the sphere of the percussion blow, the originator of the tone, to the violin string pushed from its position of unstable equilibrium, and the remainder of the body, together with its surroundings, to the sounding board which shares in the vibrations. Other things being equal if the resonator of the violin remain constant, the intensity of a tone arising from the blow upon the string depends upon the energy of the vibrating string. In the same way the intensity of the percussion-note in deep percussion is proportional to the energy of the sphere of the blow. Now, since, as we saw above, this energy can be estimated according to the formula $E = \frac{\text{mass} \times (\text{velocity})^2}{2}$,

so, other things being equal, the size of the sphere of the blow, so far as it involves tissues capable of vibrating, i. e., air-containing tissues, is all important for adjusting the strength of the percussion blow. Hence, the author considers that it is possible, as has been done now for years, to outline by means of percussion the boundaries of the deep-lying organs, especially the heart; and that Weil is correct in his contention that another explanation, which could only consist in assuming a tone-dulling influence of the solid organs, can be excluded on experimental grounds. No other explanation is logically conceivable. The fault with the authors who undertook to dispute this well-founded view seems to consist in their being unable to differentiate the simple action of the stroke of percussion, i. e., the primary cause of the tone, from the tone vibrations themselves, i. e., the secondary cause of the tone. Weil's teaching took an exception to this attack, but the above analysis of the physical relations is given by the author for the first time here. For the sake of clearness and simplicity it is advisable to accept the author's substitutes "sphere of the percussion blow" or "sphere of action of the percussion blow" instead of Weil's term, "acoustic sphere of action of the percussion blow," because the sphere of action is here essentially mechanical and not at all acoustic.

The necessary strength of the percussion stroke naturally depends not only upon the nature and the position of the surrounding organs, but upon the thickness of the body-wall, and especially upon the dimensions of the body. For example, the inferior lung boundary can ordinarily be easily distinguished from the liver by very light percussion, but not in very fat or edematous patients, because then the sphere of action of the percussion blow does not penetrate beyond the thick layer of the thoracic wall. In such cases only very vigorous percussion can bring out a clear, distinct pulmonary resonance, and at best the superficial as well as the deeper boundaries are very difficult and sometimes impossible to map out. It goes without saying that in percussing children the strength of the percussion blow should be modified to correspond to their smaller size.

It is evident that the strength of percussion adjusted to bring out the deep dulness is by no means always the same. Fig. 119 (see next page) will perhaps best illustrate this point:

It represents a horizontal cross-section through the thorax with the heart surrounded by the lungs. The areas of two different percussion blows are represented in the figure, one penetrating deeply (stronger percussion) and the other more superficial (lighter percussion); yet both outline the border of deep cardiac dulness at the same point, *x*, because, according to Fechner's psychophysical law, the shaded portion of the heart substance *ab* furnishes as plain a diminution of the tone to lighter percussion as the much larger portion *cd* does to stronger percussion. This essenti-

ally coincides with practical experience and best explains the remarkable dispute which has recently been so warmly undertaken over the elementary questions of percussion strengths and the percussion of the deep cardiac dulness. The author believes that there is right upon both sides, and that deep dulness can be correctly brought out by different strengths of percussion provided that the examiner has properly learned how to percuss. The quality of the examiner's ear is a very essential factor. This is evident when we remember (see p. 207) that the pitch of the percussion-note must be assumed to vary with the strength of percussion. This influence of the strength of percussion upon the pitch is one reason for the individuality of percussing for deep dulness, because each observer, depending upon the quality of his hearing, must percuss in such a fashion as to bring out varieties in notes most plainly for himself. Detailed rules for the strength of percussion are superfluous. It is fortunate that such liberty in percussion does exist, otherwise no results could have been obtained with deep percussion; and one might think, by reading many of the latest publications upon cardiac percussion, that nothing had been accomplished. Percussion must remain a free art, and the only valuable rule (p. 214) is *that the strength of percussion as well as the force with which the pleximeter is applied must be so regulated that the examiner's ear appreciates the maximum degree of the dulness and the most distinct dulness*. This may vary with the patient and with the examiner, or rather with the latter's ear, from all grades of medium strength to very light percussion, but it should never be exceptionally strong.

Goldscheider¹ has practised a so-called "schwellenwert percussion" (threshold) to determine deep cardiac dulness. He employs the lightest possible percussion, and it is actually so faint that one is unable to appreciate any distinct note over the deep cardiac dulness, whereas on the other side of the borders the note is just audible.

Fig. 119.—Diagram to show that different strengths of percussion may outline the same deep heart dulness.

He, therefore, employs for the deep dulness the rules which the author has suggested for the superficial dulness. (See p. 210.) The deep dulness may doubtless be outlined with even as light a percussion as the author ordinarily employs for mapping out the superficial dulness, and, in fact, the author has several times convinced himself of this possibility.² But, on the other hand, there are many cases in which this method will not accomplish any result, or at best too restricted a deep dulness or one lying too near the superficial dulness. This depends upon the peculiarity of the cases themselves; and Goldscheider acknowledges further that his lightest percussion does not always succeed. The author does not recommend Goldscheider's method, because it does not depend upon any generally applicable acoustic principles, and because it disregards the didactically important distinction between deep and superficial dulness. He does, however, appreciate its value in teaching others the disadvantage and lack of necessity of employing so strong a percussion as to be disagreeable to the patient. Goldscheider's excellent results may depend upon other peculiarities in his methods. He percusses upon the bent first interphalangeal joint of the second finger or upon a pencil-like stick obliquely applied at one end. Further he utilizes the intercostal spaces exclusively. With this method, in virtue of the small surfaces of contact of the pleximeter with the body surfaces, a comparatively elongated narrow region of the percussion blow is formed, favorable to the differentiations of the dulness. Goldscheider's method of sending rays of sound from the end of a little

¹ Deut. med. Woch., 1905, Ueber Herzpercussion, Cong. f. inn. Med., 1907; Deut. med. Woch., 1907, No. 28, p. 1122.

² In mapping out the superficial dulness one must actually percuss again, rather harder inside the deep cardiac dulness, in order to again obtain the pulmonary note, although this seems paradoxical.

stick, and, according to its position, in varying directions into the interior of the body, seems, from the physical standpoint, untenable (see p. 202), for with percussion there are no sound rays. The author's objections to sagittal percussion always perpendicular to the body surface, which Goldscheider especially recommends, and which is responsible for the term "orthopercussion," have already been expressed. (See p. 201 et seq.)

The conformity of deep percussion with the anatomic projection of the deep organs or with the results of orthodiagraphy is discussed under the comparative relations of the cardiac dulness. (See p. 201.)

If we only percuss lightly enough and with slight pleximeter pressure, *superficial dulness* is frequently quite intense. For this reason it is often called *absolute dulness*. On the other hand, deep dulness is never complete or absolute, and hence is called *relative dulness*.

The designations *absolute* and *relative dulness* should be avoided in topographic percussion, because in mapping out organs it is much more important to know whether a dulness is obtained by deep or by superficial percussion than whether it is more or less intense. Despite light percussion, superficial dulness will not be absolute if the air-containing surroundings be set in vibration.

It is easier to teach practically the other essentials to the technic of topographic percussion than to describe them. In mapping out an organ the beginner should compare the note in two places, one of which plainly lies outside and the other inside the edge of the organ to be defined. He should then percuss between these two places, gradually advancing the pleximeter parallel to the edge to be determined until one point of the boundary is determined and marked upon the skin with a pencil. In a similar way other points of the boundary are marked, and finally all are joined by a line which will correspond pretty accurately to the edge of the organ. Such a line can be represented schematically (as described above) upon a chart.

It is important to represent the points determined as round dots, because in determining the remaining points one is too easily influenced by autosuggestion from previously drawn lines.

For rapid and comprehensive registering of the results of percussion we use in the Bern clinic different colored pencils. We represent the superficial dulness obtained by light percussion by blue; the deep dulness obtained by strong percussion by red. The intensity of the dulness is expressed by varying the intensity of the color. A dulness appreciable both to deep and superficial percussion is represented by a mixed red and blue color. Even color tones and evenly mixed colors are easily made by using very soft pastel pencils and a leather stump. In order to distinguish the boundaries of organs which are palpable from those which we obtain by percussion, the former are denoted by a continuous black line. This method of representation is followed throughout this book.

A comprehension of the topographic results of percussion naturally presupposes an exact knowledge of normal visceral topography. Many anatomic facts relative to the position of organs do not, of course, apply accurately to such relations in the living body, because the position of the organs is markedly influenced by the breathing, and because even the median vital position of the thorax and of the diaphragm is quite different from that in the cadaver. This is especially noticeable in the position of the lung edges. In the first place the lung boundaries in the

cadaver assume an entirely peculiar position of equilibrium, on account of the elastic relations of the thorax and of the lungs, the rigidity of the respiratory muscles, etc. This is, or at least may be, essentially different from the median position in the living. The cadaveric position of the lung edges is generally that of exaggerated expiration. Frozen sections, inserting needles through the lung edges before opening the thorax, or

cutting windows in the thoracic wall without disturbing the costal pleura, furnish correct results. All other anatomic testimony is, in the nature of things, worthless, because as soon as the thorax is opened, the lungs are retracted, tending to assume a position of equilibrium. Topographic percussion is therefore a valuable aid to anatomists for determining the anatomic position of organ boundaries during life. The cuts illustrating the position of the viscera in this book are taken from the classic

plates of Luschka and the models of Ferber.¹ They have been drawn especially for clinical purposes to show the median position of the movable organs, and with particular attention to the sources of error mentioned above. The reader is recommended to study Ferber's models.

Symington's² cross-sections [or Dwight's Frozen Sections of a Child.—Ed.] illustrate the topographic relations in the child.

those with their tips freely suspended, is the eleventh. In counting the vertebral spines we generally begin with the seventh cervical. Its prominence when the head is bent forward (*vertebra prominens*) makes it easy to recognize. Where three vertebral spines are quite prominent in this region, the seventh is usually in the middle. Where the seventh cannot be positively determined, the vertebræ should be counted from below, *i. e.*, from the fifth lumbar vertebra upward. The lower angle of the scapula, with the arms hanging, ordinarily corresponds to

the seventh rib and the seventh dorsal vertebra. The base of the xiphoid cartilage can be utilized in topography, but its tip varies considerably in length and position, and is therefore unreliable.

Besides the skeletal parts we make use of so-called orientation lines. These are vertical lines which intersect the ribs at certain angles. They are the following (see Figs. 115, 116, and 117):

1. The anterior and the posterior median line.
2. The right and the left sternal line—drawn vertically through the edges of the sternum.

Fig. 123.—Topographic areas of trunk (anterior view).

3. The right and the left parasternal line—drawn half-way between the sternal border and the nipple.

4. The right and the left mammillary line (or nipple line)—drawn perpendicularly through the nipple.

5. The middle, the anterior, and the posterior axillary line—drawn through the apex and the anterior and the posterior edge of the axilla.

6. The right and the left scapular line—drawn perpendicularly through the inferior angle of each scapula, with the arm hanging down.

The position of the mammillary line is inconstant both in men and in women. The so-called *midclavicular line*, which is dropped perpendicularly from the middle of the clavicle, is therefore a more accurate landmark. A horizontal mammillary line is sometimes employed; that is, a horizontal line on the surface of the thorax, drawn through the nipples. Its position is, of course, influenced by the height of the latter. In men these are usually found to be between the fourth and fifth or upon one of these ribs (rarely between the fifth and the sixth ribs), about 10 cm. distant from the lower thoracic edge, and about 16 cm. from the lower edge of the clavicle.

The terms used in topographic anatomy are usually serviceable in topographic percussion—such as supraclavicular and infraclavicular fossæ, supraspinous and infraspinous fossæ, interscapular space, epigastrium, hypochondrium, mesogastrium, hypogastrium, etc. (See Figs. 123 and 124.)

TOPOGRAPHIC PERCUSSION OF THE LUNGS

THE POSITION OF THE DIAPHRAGM AS DETERMINED BY ORTHODIAG-
GRAPHIC EXAMINATIONS

The situation of the lung borders depends upon the position of the diaphragm, which in turn is essentially connected with the position of the dome of the diaphragm. Yet the dome's pronounced convexity precludes any close parallelism between it and the lung borders. Hence, the results of orthodiagraphic examinations of the diaphragm (see p. 227) may well be presented here as anatomic studies upon the living in order to round out our anatomic knowledge of the topographic percussion of the lungs.

By means of orthodiagrams Dietlen¹ determined the highest point of the diaphragm upon each side and tabulated his results as follows:

AVERAGE POSITION OF THE DIAPHRAGM. ESTIMATED IN PER CENT. OF THE NUMBER
OF CASES EXAMINED.—(Dietlen.)

No. Cases.		Third Rib.	Third Intercostal Space	Fourth Rib	Fourth Intercostal Space	Fifth Rib	Fifth Intercostal Space
106	Right {	Males	25	37	38	0
70		Females	4	17	49	16	0
106	Left {	Males	10	28	60	2
70		Females	3	38	28	31

It is evident from these figures that the diaphragm has, on the average, a higher position in women than in men (see Fig. 135, p. 232); that the size of the body has no influence, and that the shape of the thorax is of more significance; thus, the long narrow trunk corresponded more frequently to a low-placed and the short, broad thorax to a high-placed diaphragm. Dietlen, however, did not find this latter relationship nearly so constant as he did the connection between the height of the dia-

¹ Deut. Arch. f. klin. Med., 1906, vol. lxxxviii.

phragm and the age; thus, with increasing age the diaphragm is placed lower. This entirely agrees with anatomic and percussion studies. The highest positions of the diaphragm (third rib and third intercostal space) occurred only in females and in the four earliest decades. From orthodiagraphic studies upon the relative dislocation of the heart (see Fig. 132, p. 231) it is evident that the dome of the diaphragm is, as a rule, depressed in the erect position.

NORMAL LUNG BORDERS

The boundaries of the lungs normally move with respiration; hence we must distinguish, on the one hand, an *expiratory* and, on the other, an *inspiratory* position. This distinction is especially important for determining the mobility of the lung edges. In general, the mean position of the lung borders when the patient breathes superficially is sufficient for most purposes. The excursion of the lungs is then hardly greater than the limits of error which are inherent in percussion. The boundaries designated as normal correspond to such a mean position of the lung edges.

Fig. 125.—Normal percussion boundaries of the lungs, liver, and spleen, and Traube's space (anterior view).

We usually determine the inferior boundaries of the patient's right lung (the lung-liver boundary) anteriorly while he is lying down; posteriorly, while he is sitting or standing. Such a boundary line intersects the parasternal and midclavicular lines at the upper edge of the sixth rib; the axillary lines, at the eighth to ninth ribs, the scapular line, at the tenth rib; the posterior median line, at the eleventh vertebral spine. The border, therefore, is very nearly horizontal. (See Figs. 125, 126, and 128.)

The precordial edge of the left lung forms a notch within which the heart lies directly against the thoracic wall. This notch corre-

sponds to the so-called *superficial cardiac dulness* (Figs. 125 and 126). The border of the lung bounding this area lies above at the left edge of the sternum, upon the fourth rib, and runs from there horizontally to the left; at the parasternal line it curves downward to the level of the sixth rib, and then takes the same course as the inferior border of the right lung. For practical purposes we may assume that the inferior lung edge, with the exception of this notch about the heart, follows practically a horizontal and symmetric course upon both sides. The edge of the left lung which forms this notch can be easily and accurately differen-

Fig. 126.—Percussion boundaries of the lung, liver, and spleen, and Traube's space (from the left side).

tiated from the superficial cardiac dulness; but farther to the left the loud, resonant note of stomach is apt to confuse the percussion. From the axillary line backward it is easier to define the edge of the lung because the spleen, the powerful muscular masses of the quadratus lumborum, and the lumbar portion of the diaphragm lie below the lung.

The anterior lung borders run almost vertically beneath the sternum (Fig. 120), and are not accessible to percussion because only a small space exists between them, and because an exact localization of the percussion stroke upon the sternum is very difficult. The bone vibrates to percussion more or less as a whole, like a great pleximeter, and transmits

the vibration widely over the surface. The superficial cardiac dulness can be percussed accurately only when a considerable part of that bone overlies or is bounded by dull-sounding tissue. (See Figs. 139, 142.) For this reason the right border of the superficial cardiac dulness ordinarily corresponds to the left edge of the sternum, and hence has usually little diagnostic importance.

The apices of the lungs above the clavicles form comparatively voluminous cones covered by relatively thick layers of muscle, which render the upper pulmonary boundaries much more difficult to determine as linear projections than the lower. Moreover, the trachea lies in such close proximity to the lung apices that percussion is very likely to set it in vibration. Hence the difficulty of properly percussing the apices. Figs. 125 and 128 represent the boundary lines of the lung apices in individuals who are neither too muscular nor too fat. The highest point of the upper lung border lies from 3 to 5 cm. above the clavicle.

The lung borders vary somewhat according to the age of the patient. For example, in old people the lung-liver boundary is situated somewhat lower (about one intercostal space). The superficial cardiac dulness is often somewhat diminished and situated about one intercostal space lower than in young adults. This change depends upon the diminished elasticity of the senile lung. Many clinicians denote this change as senile emphysema, provided nothing else abnormal is detected. The author doubts if such nomenclature be correct. He has been unable to determine a higher level of the pulmonary borders in children than in perfectly healthy adults.¹

ACTIVE AND PASSIVE MOBILITY OF THE LUNG BORDERS UNDER NORMAL AND UNDER PATHOLOGIC CONDITIONS

Vigorous respiration will depress the lung borders several centimeters during inspiration and elevate them the same distance during expiration (*active mobility*). Percussion will very plainly demonstrate this. In the axillary line the extreme positions of the lung border may reach 4 cm. above and below the mean, so that the total excursion may be as much as 8 cm. Litten's diaphragm phenomenon (p. 85 et seq.) is the visible expression of such excursions. Deep inspiration may almost or entirely obliterate the superficial cardiac dulness.

Change in a patient's position will demonstrate a *passive mobility* of the lungs. Changing from the dorsal decubitus to the erect posture may elevate the lung-liver boundary—or very rarely depress it. In some cases no change is noted. This variable result probably depends upon the preponderance of one of two opposing factors which influence the position of the diaphragm: (1) the weight of the liver; and (2) the increased abdominal pressure due to the contraction of the abdominal muscles in the upright posture. If the abdominal walls be muscular enough to contract vigorously in sitting and standing, a slightly higher position of the inferior lung boundary seems to be the rule, because the intra-abdominal pressure will be increased. This is especially applicable to the sitting posture, whereas if the abdominal walls be relaxed, *e. g.*, the characteristic pendulous abdomen, the opposite effect will be observed, because the weight of the liver will depress the diaphragm. Diaphragmic examinations have not invalidated these findings. They have shown regularly a descent of the heart and a flattening of the diaphragmatic arch when the erect posture is assumed. But this result

¹ Sahli, Die topographische Percussion im Kindesalter, Bern, Dalpsche (now Franckesche) Buchhandlung, 1881.

will not mean a change in these lung boundaries. One would think that while the dome of the diaphragm itself is depressed, the liver is raised by leverage on a frontal axis, elevating the diaphragm and border of the lung. Changing from the dorsal decubitus to a lateral posture will depress the pulmonary border of the uppermost lung about 3 or 4 cm. at the axillary lines. A deep inspiration while this position is retained may bring the border about 9 cm. lower than in the dorsal decubitus with median respiratory position; and with a full expiration in the latter posture the lung border may, under some circumstances, make an excursion of as much as 13 cm. By means of all these different types and degrees of lung mobility it is generally possible to demonstrate the clinically important sign of *diminished or absent lung mobility*. The mobility of the lung border is diminished in—(1) *pulmonary emphysema* and in (2)

Fig. 127.—Method of apical percussion.

partial consolidations of the lung. Although the percussion-note may not be noticeably dulled if these consolidations be scattered, such a condition may be suspected from the immobility of the border. (3) *Firm pleuritic adhesions* between pulmonary and costal pleura also prevent mobility.

Some examiners attempt to demonstrate pleuritic adhesions of the lung edge by percussing below the border determined during quiet breathing while the patient breathes deeply. If the loudness of the note be much increased with inspiration, they then claim that the lung edges are freely mobile. This method of examination, according to the author's experience, often causes error. Even if the lung be quite adherent, the intensity of the note beneath the lung border is almost certain to increase during inspiration. Such an increase does not necessarily prove a descent of the boundary, but merely suggests a thickening or

an inflation of the lung edge. In other words, a greater accumulation of air at or near the pulmonary edge influences the note, because even with the lightest percussion it is not possible absolutely to localize the percussion stroke.

A much better method for demonstrating mobility of the pulmonary border is to determine the boundary in the position of extreme inspiration while the patient holds his breath, mark it on the chest, and then do the same during extreme expiration. The best method is to utilize, in addition, the passive excursion of the lung border by turning

Fig. 128.—Normal percussion boundaries (from behind).

the patient to the opposite side from the one being examined, while he retains at the same time the position of deep inspiration, and in this way to accentuate the result. When so determined, the finding is especially trustworthy for the anterior and lateral boundaries.

ABNORMAL POSITION OF THE LUNG BOUNDARIES

Under pathologic conditions the lung boundaries may be extended as well as contracted.

Extension of the lung boundaries occurs in *emphysema*, where the lung-liver boundary may reach down to the eighth rib in the right mid-clavicular line, to the ninth or tenth rib in the axillary line, and to the twelfth vertebra behind in the posterior median line; in fact, quite to the inferior limit of the thorax. The emphysematous increase may sometimes be plainly demonstrated even at the lung apex, and over the superficial cardiac dulness, which may be either entirely or almost obliterated. Both the active and the passive mobility of the borders in

emphysema are diminished on account of the permanent inspiratory position of the diaphragm and a certain rigidity of the lung so characteristic of the disease. Emphysema is ordinarily developed upon both sides, and, as a rule, quite uniformly; but a partial emphysema does occur (perhaps incorrectly called *vicarious emphysema*), in which the changes are localized at the lung borders. Even in the common type of pulmonary emphysema the pulmonary distention is not always uniform. Percussion frequently shows that the emphysema is limited to the region over the heart, whereas the inferior lung border is not any lower than the normal. This is often seen in fat or dropsical individuals, apparently because the increased abdominal contents crowd the diaphragm upward.

In a similar manner the pulmonary boundaries are extended in attacks of *bronchial asthma* and in *obstructive bronchitis* because there is a greater resistance to the emptying (p. 96) than to the filling of the lungs (acute pulmonary distention). For analogous reasons, when a bronchus is narrowed, the affected pulmonary lobe is distended.

Certain chronic *cardiac affections*, particularly mitral lesions, lead to pulmonary distention, the lungs being permanently engorged with blood and in the condition of so-called cardiac lung rigidity; brown induration is usually present as well. The lungs in these cases resemble those of emphysema, since they are distended, their elasticity is partly lost, and they make but slight excursions.

However, only advanced cases of known induration can be distinguished by percussion.

The *acute congestion of failing compensation* can also frequently be recognized by extension of the lung boundaries and so can *pulmonary edema*, provided, of course, that the pulmonary edges in the latter condition still contain air.

The lung borders in *enteroptosis* (p. 253) are nearly always depressed.

Retraction of the lung boundaries results from the crowding of the lung edges by the neighboring parts. 1. The diaphragm will be pushed upward by all conditions which increase the intra-abdominal pressure, *e. g.*, *meteorism*, *ascites*, *abdominal tumors* (especially if situated at the convexity of the liver). The intrathoracic pressure will, therefore, approach more nearly that of the external air; so the lungs must be retracted, not only upward, but concentrically in all directions, from in front backward and toward the hilum, even enough to expose the heart to a considerable extent. 2. An *enlarged heart* (or a *pericardium filled with fluid*) can also crowd the lungs aside enough to increase the superficial cardiac dulness. (See Heart Percussion.) If such a crowding be very marked, the resulting intrathoracic pressure will elevate the inferior lung borders. 3. All processes associated with a pulmonary shrinking may occasion a retraction of the lung boundaries, *e. g.*, the *chronic forms of tuberculosis*, which produce a connective-tissue retraction of the lungs; and cases of *pleurisy* in which, after the absorption of the exudate, the expansion of the compressed portion of the lung is prevented by the formation of a firm connective-tissue coating. The shrinking usually proceeds concentrically in such conditions, so that the lungs are often retracted on all sides—that is, as much over the heart as at the inferior borders, and sometimes even at the upper borders, toward the hilum. Chronic tuberculosis frequently leads to a retraction of the pulmonary apex. Therefore the demonstration of a low position

•

of one superior lung border is of special importance for the early diagnosis of apical tuberculosis.

We must remember that the normal positions mentioned above are only averages, and that abnormally long or short chests would naturally modify the position of the lung borders in relation to ribs, although the condition could in no way be considered pathologic. Errors in this respect, especially in relation to the diagnosis of emphysema, frequently occur in practice. They cannot be avoided by definite rules, but only by practical experience and by the development of a geometric vision.

TOPOGRAPHIC PERCUSSION OF THE HEART

RÖNTGEN ORTHODIAGRAMMY OF THE HEART UNDER PHYSIOLOGIC AND PATHOLOGIC CONDITIONS: RESULTING CONCLUSIONS AS TO ITS SIZE AND RELATIVE POSITION

As we shall see, only certain limited, though practically important, conclusions regarding the size and position of the heart can be drawn from topographic percussion. Hence the importance of Röntgen orthodiagrammy, the elaboration of which we owe to Moritz, for it furnishes us with a means of studying normal and pathologic anatomy in the living subject, thus eliminating such changes as accompany death and the distortion necessarily entailed in postmortem examinations; and, in addition, it can be employed as a sort of control immediately after the other examination

Fig. 129.—Orthodiagram of the stomach, lung area, and diaphragm of a normal man (one-fourth natural size) (Moritz): *Cl*, clavicle; *ML*, median line; *Th*, thoracic wall; *Zw*, diaphragm; *Mr*, distance of the right border of the heart from the median line; *ml*, distance of the left border of the heart from the median line; *uQ* and *oQ*, lower and upper transverse partial diameter of the heart. The latter are drawn perpendicular to the cardiac axis. $uQ + oQ$, the diameter representing the width of the heart.

methods. Röntgen orthodiagrammy presents the relations of size and position more accurately than Röntgen photography, because the former does not exhibit the shadows due to the divergent rays, which cause much distortion.

In Röntgen orthodiagrammy the *x*-ray tube moves in a plane which is parallel to the plane of the fluorescent screen. The projection point of the vertical rays on the screen is indicated by a rod which is attached to the *x*-ray tube, passes around the patient, and ends in a marking-point just in front of the screen. The apparatus is so constructed that, as the *x*-ray tube is moved about, the marking-point always touches the fluorescent screen at the place where the vertical rays are projected. In

this way the shadows cast by the bony landmarks and the more solid organs are outlined on tracing paper attached to the fluorescent screen or on the skin of the patient. As shown in the accompanying illustrations, numerous heavy dots mark the contours, and the outlines are completed by joining them.

One of Moritz's figures, an orthodiagram, showing the size and position of the normal heart, is reproduced here. (See Fig. 129, p. 229.) The oval heart shadow seems to be suspended within the thoracic skeleton by the cardiac hilum, which is composed of the mediastinum and its great vessels. Fig. 120, p. 218, a graphic representation of the organs in situ, should be compared to understand properly the significance of the individual parts of the shadow. Attention should be called to the fact that the right and left portions of the inferior borders of the heart are located with accuracy, despite the presence of the hepatic shadow. Mere percussion is not sufficient to do this except to a much more limited extent. The points of

Left ventricle

Fig. 130.—Schematic view of the cardiac region from the left, the lung having been removed (Moritz).

the lower parts actually determined orthodiagraphically are represented here and in the following orthodiagraphic figures by heavy dots. The meaning of the artificial lines used for measurements is indicated in the legend, and the manner in which they are drawn is apparent from the diagram. Fig. 130 is a schematic lateral view of the cardiac region. Fig. 131 is its Röntgen orthodiagram, the direction of the ray being from right to left.

Dietlen¹ gives the following figures for the measurements of an orthodiagram of a normal heart:

MEASUREMENT OF THE ORTHODIAGRAPHIC HEART SILHOUETTE IN HEALTHY ADULT MALES

(Abbreviations are explained in Fig. 129 and the following pages and in the foot-note upon page 236.)

Height cm.	Weight kg.	Mr cm.	MI. cm.	Tr = Mr. + MI. cm.	Length cm.	Width = oQ + mQ cm.	Area sq. cm.
145-154	mean 47	3.7	8.5	12.2	13.4	9.6	103
155-164	" 57	4.2	8.7	12.9	14.0	10.2	111

175-187	" 71	4.5	9.3	13.8	14.9	11.0	131

¹ Deut. Arch. f. klin. Med., 1906, vol. lxxxviii.

The cardiac measurements increase in proportion to the stature and weight of the individual, the influence of the latter being more important than that of the former. Dietlen found that the measurements were about 0.5 cm. smaller in women than in men of the same height and weight; that they were somewhat smaller in youths than in adults of the same height; and that they were greater in elderly individuals of middle age.

Fig. 131.—Orthodiagram of the thorax taken from the side (corresponding to Fig. 130), with well-developed retrosternal (*Rst.*) and retrocardiac (*Rc.*) spaces: *W*, anterior margin of the vertebral column; *Z*, diaphragm in position of expiration (one-third natural size).

Moritz¹ and Dietlen² have studied, with the assistance of this method, the changes in size and position of the heart under physiologic and pathologic conditions. A short résumé of their most important conclusions follows: In changing from the recumbent to the erect posture the heart sinks 2 to 4.5 cm. (Fig. 132). All the abdominal viscera, especially the liver with the diaphragm, participate in this descent. According to the author's percussion, however, and he believes that per-

Fig. 132.—Orthodiagram of a normal heart. Red line, in horizontal position; blue line, in upright position (two-ninths normal size) (Moritz).

cussion can be relied on in this case (see p. 225), the shifting of the lung borders proceeds in the reverse direction. With the assumption of the erect posture the heart as it descends assumes a more vertical position, revolving on a sternovertebral axis, passing through the great vessels, so that the transverse diameter of the shadow is shortened by 2.5 cm. (Fig. 132). In fact, all its diameters are frequently slightly

¹ Deut. Arch. f. klin. Med., vol. lxxxi, p. 1 et seq.; vol. lxxxii, p. 1 et seq.; Zeit. f. klin. Med., vol. lix; Deut. Klinik, Methoden der Herzuntersuchung, 1906.

² Deut. Arch. f. klin. Med., vol. lxxxviii.

diminished. Moritz attributes these reduced measurements to an actual diminution of the size of the heart, due essentially to its decreased filling, dependent upon an increased accumulation of blood in the territory of the vena cava inferior.

When the patient lies on his side (Figs. 133 and 134), orthodiagraphy shows the same lateral displacement of the heart as does percussion. (See p. 240.)

Fig. 133.—Orthodiagram of the normal heart (nineteen-year-old male). Red line, dorsal position; blue line, right lateral position (two-ninths natural size).

Fig. 134.—Orthodiagram of the normal heart (nineteen-year-old male). Red line, dorsal position; blue line, left lateral position (two-ninths natural size) (Moritz).

The position of the diaphragm in respiration has, as is to be expected, a decided influence on the position of the heart. With the aid of the orthodiagraph it is plainly demonstrated that the heart sinks with inspiration, and at the same time undergoes those changes in shape and size which have been described as characteristic of shifting from the horizontal to the vertical posture. Moreover (as, for example, in old age), a lower position of the diaphragm is associated with a corresponding lower

Fig. 135.—Red line, orthodiagram of a healthy girl's heart, age twenty; blue line, orthodiagram of a healthy man's heart, age thirty (two-ninths natural size).

position of the heart. Concerning the relations of the position of the diaphragm the reader should compare the notes upon orthodiagraphy of the diaphragm (p. 222). According to Dietlen, an orthodiagram shows that the heart is in general placed more horizontally when the diaphragm is low (except in emphysema and asthma, see below).

This writer found the heart-shadow about one intercostal space higher in females than in males (Fig. 135). He attributes this to the higher position of the diaphragm in women. (See p. 222.)

Moritz and Dietlen examined the heart in pathologic conditions, among others, in asthma and emphysema. In both the latter they found a narrow, vertically placed heart situated low down in the thorax. A similar finding is observed in pneumothorax and in healthy, slender young subjects of both sexes, especially in young girls. A tightly laced corset crowds the heart upward.

The excursion of the heart shadow between systole and diastole amounts to only a few millimeters. This explains why one cannot elicit a difference in percussion between the cardiac phases.

The apex impulse almost never corresponds to the position of the apex in the orthodiagram of the heart, but is usually about an intercostal space higher and nearer the median line. Dietlen explains this more median position of the apex impulse as follows:

At the apex the excursions of the heart wall are at a maximum, so that there is a distinct difference between the position of the heart, which corresponds to the movement of the cycle coinciding with the apex-beat, viz., systole, and that which corresponds to the shadow represented orthodiagraphically, viz., diastole. The author's objections to this explanation will be found below.

Dietlen explains the high position of the apex-beat in relation to the lower edge of the heart shadow by the fact that the latter coincides with the border of the right ventricle, while the former belongs to the left ventricle. The author believes that the apex impulse is so frequently situated nearer the median line than the left border of the cardiac orthodiagram essentially because the apex itself is covered by lung tissue, so that the outer portion of the apex impulse is inaccessible to palpation. Therefore, the apex impulse in the strictest sense, *i. e.*, the strongest pulsation within the left cardiac border, can be appreciated only when the heart is entirely, or almost entirely, exposed. In the last edition of this book the author described a similar discrepancy between the results of palpation and of percussion, so Dietlen is wrong in ascribing to the author the statement that the position of the apex impulse is identical with the left border of the heart. On the contrary, the author has maintained, on the evidence of percussion, that the apex impulse does not always coincide with the extreme left of the cardiac wall, though he acknowledges that he did not lay this down as an arbitrary rule.

The author prefers his own explanation of this peculiarity (overlapping lung) to that of Dietlen (difference in the systolic and diastolic position of the apex). Against the latter may be argued that the excursions of the heart boundaries in the region of the apex are very slight, as demonstrated by the orthodiagram, and that the apex impulse coincides with the closure time when the heart has not yet contracted. (See the section upon the Apex-beat.) Moreover, it must be added that, in the cases where the apex impulse coincides with the external border of cardiac dulness, both these points not infrequently lie outside the orthodiagraphic projection of the heart shadow upon the anterior thoracic wall. The reason for this is, that if the heart apex lie at a point where the thoracic wall has already curved sharply backward from the frontal plane, the boundaries of the deep cardiac dulness naturally extend beyond, and the apex impulse lies outside of, the frontal projection of the heart, foreshortened in the orthodiagram upon the sharply bent thoracic surface (cardiac dulness larger than the heart; see p. 239).

NORMAL SUPERFICIAL AND NORMAL DEEP CARDIAC DULNESS

Superficial cardiac dulness is the dulled area which corresponds to the notch of the left lung about the heart (Figs. 125 and 136). Its extent really tells more about the position of the lung edge than about the size of the heart. Nevertheless, if the heart be enlarged or if the pericardium become distended with fluid, the edges of the lung will be pushed back and the superficial cardiac dulness be increased. Certain cautions are necessary to prevent mistakes in estimating the size of the heart or pericardium from the extent of this superficial cardiac dulness. For example, despite an enlarged heart, the superficial cardiac dulness is not necessarily increased in emphysema, nor need it be if the lung edges in the neighborhood of the heart be fixed by pleuritic adhesions. The deep dulness is more important in estimating the size of the heart and the contour of the pericardium. Deep cardiac dulness is never very intense, but is always modified (a so-called relative dulness).

The beginner often finds it very difficult to determine. The superficial cardiac dulness, on the contrary, is frequently absolute, and therefore easier for the beginner's ear to appreciate. Both varieties of dulness should, therefore, be mapped out upon the chest. The superficial often confirms the results of the deep percussion.

In estimating both superficial and deep dulness it is advisable to follow exactly the method described upon p. 210 et seq. The form and size of the superficial dulness, also called the small cardiac dulness, have already been described in the section on Topographic Percussion of the Lungs. (See Fig. 125, p. 223.) Fig. 136 represents the relations of the superficial and the deep or great cardiac dulness in the average healthy adult. The boundary of the latter runs from the upper edge of the third left rib nearly parallel to the border of the superficial

1

Fig. 136.—Superficial and deep cardiac dulness under normal conditions.

cardiac dulness, bends toward the left in a curve, with the convexity outward, becomes perpendicular slightly inside the midclavicular line, and ends near this point at the apex-beat. The heart is bounded below by the liver, so that the deep dulness throughout its whole extent (see Fig. 136), like the superficial, merges below into the hepatic dulness and cannot be differentiated from it. If tympanitic intestines overlap the liver or crowd it upward and to the right, superficial percussion will generally evoke a loud tympanitic note just below the heart. Fig. 140, p. 245, illustrates such a condition, although it should be noted that whereas in this figure the region of the heart apex seems to be entirely covered above, it can project beyond the lung edge below, in which case the inferior cardiac boundary exhibits throughout its entire extent the characteristics of a superficial dulness. This so-called "inferior cardiac boundary" will always be difficult to distinguish from the dulness of

the liver edge. Most writers limit the right boundary of the deep dulness at the left sternal border; nevertheless, according to the author's experience, the majority of healthy adults show a slight dulness up to or just beyond the right sternal border (Fig. 136).¹ But in many cases the whole extent of the sternum furnishes so resonant a note that the deep cardiac dulness is really limited by the left sternal border. (See Topographic Percussion of the Lungs.) These individual peculiarities depend upon the vibration of the sternum, upon the thickness of the layer of lung covering the heart, etc.; nevertheless the author regards it as the rule that the deep dulness can be traced as far as the right edge of the sternum and even $1\frac{1}{2}$ cm. beyond. The reason other observers obtain different results, limiting the right edge of the deep cardiac dulness at the left edge of or in the middle of the sternum, is because they do not follow the methods for eliciting deep dulness which were described upon p. 210 et seq. In determining the upper borders of the deep dulness the sternum transmits the blow so deeply that a lighter percussion becomes necessary, even though deep dulness is to be elicited. It was established upon p. 211 that deep dulness should never be determined by very vigorous percussion.

The device to simplify cardiac percussion by having the patient bend over and assume the expiratory position is discussed under Active and Passive Mobility of the Superficial and Deep Cardiac Dulness.

To determine the deep cardiac dulness in women with well-developed breasts, the left breast should be lifted up and held away from the field of examination.

Percussion is not concerned with the excursions of the heart from diastole to systole. According to orthodiagraphic examinations, these excursions amount to but a few millimeters (see p. 233), and percussion is too inaccurate a method of examination to distinguish such differences, even if we disregard the difficulty of undertaking so fine a distinction within the cycle of a single cardiac revolution.

Variations of the thoracic dimensions in different individuals make the conclusions to be drawn from deep cardiac percussion still more doubtful. The heart boundaries are ordinarily mapped out in accordance with the orienting lines of the body, *e. g.*, the position of the left border of the heart in reference to the mammillary line. This sometimes leads to erroneous conclusions. Although, as a rule, the left border of the deep cardiac dulness lies somewhat inside the mammillary line, it is self-evident that if the mammillary line lie near the midline, even a normal heart would extend beyond it. Even the midclavicular line is not absolutely constant, because the length of the clavicle sometimes varies out of proportion to the breadth of the thorax. If the sternum be broad, a dulness beyond the right sternal edge is more significant than if it be narrow. Hence the importance of the absolute size of the cardiac dulness.

To estimate this, the author recommends determining, in as close accord with the normal orthodiagraphic measurements as possible, the distances from the midsternal line to the extreme left and to the extreme right limits of the deep cardiac dulness, as well as the distance from the highest point of the deep cardiac dulness upon the middle of the sternum to the apex impulse or, if it be possible to percuss out the inferior cardiac boundary (see p. 234), to the lowest point of the latter.

¹[I determined the right border of deep cardiac dulness in 60 boys between the ages of fifteen and twenty-one. It extended to or beyond the right sternal edge in over 70 per cent. of them.—ED.]

Dietlen's table (p. 230) furnishes approximately average figures for these distances: *Mr*, *MI* (width to the right and left of the median line), and *L* (length).

According to the author's experience these orthodiagraphic normal measurements correspond sufficiently accurately to those mapped out in the figure representing the results of deep cardiac percussion. The opportunity to compare the measurements obtained during life with those of the anatomic size and position of diseased hearts in pathologic cases at autopsy clearly proves that deep percussion is a very trustworthy method, provided, of course, the examiner be sufficiently skilled in the technic.

The statements presented here differ in several particulars from those advanced recently by Moritz and Dietlen,¹ which were based upon their examinations controlled by the corresponding orthodiagram. The main differences are, therefore, summarized in what follows. They base their examinations upon orthodiagraphic heart figures (see p. 229 et seq.), and believe that the results of their percussion coincide almost perfectly. They accordingly represent in their articles figures of cardiac dulness which correspond more or less accurately with the real orthodiagraphic heart silhouettes.

Thus, their figures are depicted, for the most part, as open above, with the lateral borders of the heart proper prolonged in broken curved lines corresponding to the boundary of the orthodiagraphic shadow of the hilum of the heart (see Fig. 129, p. 229), and running parallel to the sternum. In many cases, to be sure, these mediastinal boundaries are not continued very far upward; but stress is laid upon percussing out the right "heart vessel angle," because the latter forms the basis for the linear measurement of the heart dulness.² In many cases between the two heart vessel angles a horizontal upper cardiac boundary, represented by the dotted line in Fig. 129, p. 229, can be distinguished from the "hilum dulness." Moritz and Dietlen further find, corresponding to their orthodiagraphic heart figure, and differing from the heart figure as represented by the author (Fig. 136, p. 234), that the right lateral deep cardiac border forms an acute angle with the right inferior lung border (Fig. 129, p. 229). The third difference is that Moritz and Dietlen "in most cases" map out the inferior cardiac border in the region of the apex by percussion and quite in accord with their orthodiagraphic results, whereas the author has explained that it is impossible to percuss out the inferior heart border in the region of the apex except in the cases which present a considerable portion of the inferior cardiac border free from the left lobe of the liver.

Corresponding to the Moritz-Dietlen pictures, the author agrees that from the heart upward the sternum, together with a very narrow zone outside of and along each sternal edge, does furnish to *moderate percussion* a note which is slightly dull compared to that obtained further to the sides. This dulness can be accredited, perhaps in part, to the contents of the anterior mediastinum, *i. e.*, the heart hilum, but the author does not believe that it is correct, at least under normal conditions, to identify this dulness with the orthodiagraphic heart hilum. Now the sternum, especially its superior portion, is fixed by a firm buttress, the short immobile first rib, so that the percussion-note over it and in its immediate vicinity must be dulled. Who, therefore, can distinguish how much of such a dulness is produced by this peculiar conformation of the chest-wall and how much by the great vessels? For normally the dulness is rather slight and indistinct. In addition to this, the actual topographic percussion of organs is scarcely feasible here when we consider that the great vessels run directly backward and are hidden under quite thick layers of lung which almost meet in the median line, as is shown by Fig. 120, p. 218. Under pathologic conditions, such as dilatation of the arch of the aorta or dislocation of the mediastinum by pleural exudate, etc., percussion and usually even superficial percussion, can bring out the dulness because the lungs are forced apart. This zone of dulness has already been described in earlier editions of this work, and in this edition it will be discussed further

¹ Moritz, Arch. f. klin. Med., vol. lxxxviii, 1906; Dietlen, *ibid.*; also Dietlen, *Methods of Examination of the Heart*, Deut. Klinik, 1906.

² They draw the long diameter of the heart figure (see Fig. 129, p. 229) from the right "heart-vessel angle" (heart-cava angle) to the point of the figure farthest downward and to the left, and they represent the width as the sum of the two partial diameters perpendicular to this diameter.

under the special discussion of the results of percussion. As the author does not consider that this mediastinal dulness which exists under normal conditions can be utilized for diagnosis, he naturally cannot accede to the Moritz-Dietlen proposition to attribute topographic value to the angle which they outline by percussion between the lateral heart borders and the border of the heart hilum, so as to be able to measure the heart exactly as in the orthodiagram, Fig. 129, p. 229, nor can he, as an instance in point, utilize the right "heart-vessel angle" (heart-cava angle) as a starting-point for estimating the length of the heart. Neither can he comprehend how these writers can prolong the heart dulness into the hilum dulness, as mentioned above, and then, despite such a continuity (see the plates in Dietlen's work), percuss out the heart hilum from the upper cardiac border.

The author also takes exception to the next two deviations from the usual interpretation which these recent studies have advanced, viz., that percussion brings out the existence of an acute instead of an obtuse or at most a right pulmonary cardiac angle between the right inferior lung border and the right border of deep cardiac dulness. Viewed in the frontal plane, this angle is plainly acute, as is evident from the consideration of both anatomic and orthodiagraphic studies. (See Figs. 120, p. 218, 129, p. 229.) Viewed, however, in their three dimensions, this apparent discrepancy is explained; because if one percuss just to the right of the right border of deep cardiac dulness in continually lower horizontal levels, the dulling influence of the liver convexity entering the area of the percussion blow is more and more apparent, the lower one percusses until the acute angle becomes plainly blunt or obtuse. (See p. 210 et seq., *The Laws of Deep Percussion*.) Another objection is that this cardiohepatic angle frequently lies beneath the sternum in its whole extent, and such a position is inaccessible to deep percussion, since pronounced lateral vibrations are transmitted too widely over the sternal surface to render an accurate outline possible. Normally, therefore, according to the author, the acute heart-liver angle evident in the orthodiagram cannot be demonstrated by percussion. Under pathologic conditions, on the contrary, the oblique inclination of the right heart border outlined upon the right thoracic wall may be so pronounced that even an area of superficial dulness can be demonstrated there, as in Fig. 142, p. 247.

The third point in which the author differs from the views of Moritz and Dietlen concerns the interpretation of the results of percussing the inferior heart border in the region of the apex. As already explained (see p. 234), if the left lobe of the liver be slightly pushed to the right, the author believes this boundary accessible to percussion, but this is rarely the case. They even claim to be able to differentiate by percussion the lower heart border from the left lobe of the liver (Moritz, *Deut. Klinik*, *loc. cit.*, p. 523; Dietlen, *loc. cit.*, p. 293). From the standpoint of physics this seems quite incomprehensible. It is impossible to percuss the boundaries between two solid organs.

These two writers next endeavor to support their entire presentation by the accurate conformity of the results of their percussion with orthodiagraphy. They attempt to demonstrate statistically such an accord by tabulating the percentage of cases in which the different orthodiagraphic diameters of the heart shadows (see Fig. 129, p. 229) were correctly percussed, and by comparing the average error of percussion with the orthodiagram taken immediately afterward. They considered the diameters correctly percussed if the difference from the figures derived from the orthodiagram did not exceed 0.5 cm. They designated as the total linear error of each percussion of the entire heart the sum of the linear errors in excess of 0.5 cm., and evidently this total was constructed without regard to the character of the error. Employing this method of control, their results were excellent. A verdict of correspondence of percussion with orthodiagraphic examinations based upon such results seems, however, somewhat too optimistic. Statistics in such comparisons have the peculiarity of confusing rather than elucidating the relations. The main question is apparently not in what percentage of the cases the different heart diameters were found to be correct, i. e., in accordance with the criterion assumed, to vary less than 0.5 cm. from the corresponding orthodiagram; nor is it the main interest to know how great the average linear total errors were in the cases examined, but the cardinal point is to know how large the maximum error of percussion may be. Before the introduction of orthodiagraphy we already knew that the results of deep cardiac percussion conform accurately enough with the postmortem findings to warrant our trust in this method of examination, and this conformity is upheld by the experience at the Bern clinic year in and year out. It is, on the contrary, much more important to know to how great a degree one can err with percussion. Statements in regard to the possible maximum error, to be sure, do appear in the above-named studies; but in their conclusions too little importance is attributed to them. The great errors are

the sources of erroneous percussion diagnoses. Now it is evident that in percussing the different diameters of a heart one does not commit great errors throughout. Let us assume that for one diameter we have committed a great, perhaps the maximum, error possible, although most of the other diameters have been correctly percussed. Under some circumstances so great a mistake of even a single diameter involves an entirely incorrect percussion diagnosis, and yet if all the diameters except one were correctly estimated, the result would seem to be quite insignificant, provided we estimated the heart percussion in accordance with the above-described summation of the total linear errors of percussion obtained by adding the total errors of the different diameters. We should then arrive at the erroneous conclusion that percussion in this case had succeeded well. If, however, we acknowledge that these linear totals in cardiac percussion in reality depend upon a mistake in a single diameter, the judgment of the results of percussion will naturally be much less favorable. The question of the reliability of percussion is obscured by this manner of reckoning. The obscurity is deepened when an attempt is made to determine the mean linear totals of error for definite age subdivisions. It is perfectly conceivable that judgment of the reliability of percussion would be still more favorable by continually multiplying the number of cases used for the estimation because the gross errors would become more and more insignificant compared to the larger number of approximately accurate estimations. But how can a clinician be satisfied that percussion becomes more accurate when it is simply a theoretic improvement which depends entirely upon an increase in the amount of statistical material and when practically errors as great as 2.5 cm. (Moritz) may occur in an individual case, although the mass of statistics seem to prove that such errors are unimportant and negligible? Besides which, errors of percussion which do not exceed 0.5 cm. have been disregarded in each instance and considered as equal to zero, although it would be mathematically correct to consider such errors in summing up the total linear error.

The method of deep percussion should not be balanced in the scales of statistics, especially if such statistics be derived from approximately normal cases. The actual valuation of percussion must be determined from pathologic cases submitted to the control of either anatomic or orthodiagraphic examinations. Autosuggestion, which must play some part in normal cases, is thus excluded. The two writers admit that their results were less trustworthy in pathologic cases.

Unfortunately, even these latest studies cannot alter the author's former opinion of the reliability of deep percussion of the heart. Moritz's and Dietlen's actual findings are in accord with this opinion, although their conclusions are at variance. Deep percussion of the heart supplies results approximating the actual condition, *i. e.*, the anatomic position or the orthodiagraphic projection; but under certain circumstances these results may be accompanied by grave errors as to the size of the cardiac dulness. No statistics can bridge over this gap in percussion,—a fault shared by every other clinical method of examination,—but we must depend only upon an increasing experience in the source of error which permits anticipating it in individual cases and recognizing the cases in which we can make use of percussion results only with reserve.

It is, therefore, important to study briefly these sources of error. Instances in point are abnormal overlapping of the heart by the lungs and abnormal conditions of the thoracic wall. The existence of the former abnormality may, in some cases, prevent the determination of any deep cardiac dulness, and in others, decidedly diminish it. Under these circumstances, which one can usually recognize by the peculiarity of the superficial dulness, it is a good plan to accentuate the percussion stroke and thereby force its sphere of action deeper. But such a plan has its limitations, for in spite of every caution (light application of the pleximeter), with too vigorous percussion it is not always possible to hinder the transmission of the percussion blow too widely over the body surface and so prevent the outlining of deep bor-

ders. The condition and the shape of the thoracic surface can make cardiac percussion more or less deceptive or falsify its results. Well-developed breasts or the fatty tissue of a stout man often render accurate percussion impossible. Here, too, by increasing the strength of the percussion blow, we may attempt to force its sphere of action deeper, but this device succeeds only up to a certain extent, for the same reason as mentioned just above. Certain deformities in the thorax in the neighborhood of the heart will naturally increase the difficulty of percussing the deep cardiac dulness. The existence of a so-called "heart hump" (see p. 34), dependent upon an enlargement of the heart, is another example. So are rachitic thoraces, because, as we shall recognize later under comparative percussion, very pronounced convexity of the chest walls dulls the percussion-note. (See p. 259.) An abnormal rigidity of the bony thorax will also present an obstacle to percussing the deep borders because the inflexibility naturally favors the lateral action of the percussion blow.

In conclusion, especial attention should be paid to the peculiar relations of size of the deep cardiac dulness which arise to a certain degree from purely geometric causes, when the left cardiac border projects beyond the sharp curve of the thoracic wall. This difficulty occurs

Fig. 137.—Relation of the size of the deep cardiac dulness in small children. The border of the maximum deep cardiac dulness comes to *f*, situated at the sharp convexity of the thoracic wall. As a result, the cardiac dulness seems much larger than is the heart or its orthodiagraphic frontal projection.

—(1) When the sphere of action of the percussion stroke is large in proportion to the size of the chest (as in small children); (2) when the heart is decidedly enlarged to the left, so that it projects into the lateral thoracic region, and finally (3) when the thoracic cross-section is more rounded or oval in shape, with a longer anteroposterior than transverse diameter. Such relations are well represented in the accompanying figure of a child's thorax.

The size of the dulness bears no relation to a frontal projection of the heart, but extends beyond it. Now, since the thickness of the lung covering at the border is unknown, it is not possible to estimate the actual size of the frontal projection of the heart. But even such cases need not cause mistakes in estimating the size of the heart, provided one always bears in mind the geometric relationship and has collected sufficient experience in regard to the disproportionate size of the deep cardiac dulness in normal children and in cases where the heart (the apex-beat) reaches well around into the lateral region of the thorax.

These are all examples of conditions in which uncertainty of the percussion is unavoidable, and in which the most accurate percussion represents the boundaries as too large or too small as contrasted with the frontal projection of the organ. None of the new modifications of

the methods of percussion for which so much has been claimed can overcome these difficulties, because none of them offers anything actually new. The clinician's task is to guard against drawing false conclusions from such percussion results, and to learn in what cases the results of deep percussion are and are not reliable. The great secret of the art of percussion consists in considering the results only as one sign and in critically examining these results before they are employed in diagnosis. Then we need not be deceived by deep percussion of the heart, even if we do denounce the reported practically complete conformity with orthodiagraphy.

ACTIVE AND PASSIVE MOBILITY OF THE SUPERFICIAL AND DEEP CARDIAC DULNESS

The heart borders, like those of the lungs, change their position actively with respiration and passively with change of the patient's position. Active mobility concerns both the respiratory overlapping of the heart by the lung edges and the movement of the diaphragm, and with it of the heart, while passive mobility influences the displacement of the lung borders and the accompanying position of the heart. The orthodiagraphic examinations (see p. 229 et seq.) furnish the most valuable information in regard to the displacement of the diaphragm and the heart.

The boundaries described above are estimated during quiet breathing in the dorsal decubitus. Deep inspiration diminishes the size of the superficial cardiac dulness more or less decidedly, or even obliterates it. Forced expiration produces the opposite effect, and in rare cases the right edge of the lungs retreats so far that a superficial dulness appears to the right of the right sternal edge. Inspiration depresses the deep cardiac dulness from 2 to 4 cm., usually narrows it, and makes its left border steeper. Therefore percussion during forced expiration (without exerting abdominal pressure) will sometimes reveal the true size of a heart which is extensively covered by the lungs. Moritz and Dietlen's orthodiagraphic examinations show that in this experiment the right border retains its position while the left border moves upward and outward. This must naturally be considered in estimating the significance of the finding.

In the left lateral posture the heart falls to the left and displaces the anterior edge of the left lung. The anterior edge of the right lung is only exceptionally found beyond the left sternal edge, because its excursion is normally limited by the line of the pleura beneath the sternum. (See Fig. 120.) Therefore in left lateral positions both the superficial and the deep cardiac dulness are increased to the left.

In right lateral positions the opposite displacement occurs. Both the deep and the superficial dulness will reach beyond the right of the sternum, while the superficial dulness to the left of the sternum may entirely disappear. Moritz' orthodiagraphic examinations¹ confirm these findings in the lateral posture completely. (See Figs. 133 and 134, p. 232.)

Changing from the recumbent to the sitting posture does not produce any constant change in the form or size of the cardiac dulness. The change in shape and position of the heart demonstrated by the

¹ Deut. Klinik, Methoden der Herzuntersuchung, 1906, Figs. 50 and 51, p. 504.

orthodiagram (see p. 231) can sometimes be elicited by percussion (depression, diminution of the size and especially narrowing of the deep cardiac dulness in the sitting posture). Both the superficial and the deep dulness may, on the contrary, seem somewhat more intense in the upright posture. If the patient bend forward, both are increased, because the heart pushes the lungs aside, approximating itself more completely to the anterior thoracic wall. Where emphysema or thick thoracic walls obscure the percussion in the recumbent posture, sitting up and bending forward may be helpful. To prevent mistakes the patient must be careful not to bend sidewise or twist his back, for we must remember that in such a position a normal heart will furnish a broader and more intense dulness.

The absolute measurements of the mobility of the superficial and the deep cardiac dulness vary so much with the individual that the figures would be superfluous.

PATHOLOGIC CHANGES IN THE SUPERFICIAL AND DEEP CARDIAC DULNESS

Diminution and Disappearance of the Superficial and Deep Cardiac Dulness

In *advanced emphysema*, in *left-sided pneumothorax*, in *pneumopericardium*, and in *precordial emphysema* both the superficial and the deep cardiac dulness may be either diminished or entirely disappear. The cardiac atrophy which is sometimes observed at the autopsy table is too slight to be recognized by percussion. *Emphysema* also causes an especially low position of the cardiac dulness, on account of the deep position of the diaphragm and because the heart is covered by the lungs. Frequently no deep cardiac dulness can be made out, and the superficial, if present, may appear only at the fifth or even the sixth rib. In interpreting the relations it should be remembered that orthodiagraphy has established that in emphysema the heart is situated low down and lies vertically, so that the frontal projection appears narrowed. (See p. 233.) In *left-sided pneumothorax* we should expect that at least a part of the superficial cardiac dulness would persist, because the normal division line of the pleura, which would divide the superficial cardiac dulness in half, is shifted (Fig. 120). As a matter of fact, however, left pneumothorax almost always dislocates the heart, the division line, and with it the mediastinum, so far to the right that the superficial cardiac dulness to the left of the sternum may entirely disappear. In *right-sided pneumothorax* (Fig. 135) the air resonance may overlap the left edge of the sternum, in consequence of the mediastinum being pushed to the left, so that the superficial cardiac dulness will appear to be narrowed from the right. The demonstration of the dislocation of the heart as a whole (p. 249) will explain this condition. Percussion elicits an abnormally resonant metallic note (often tympanitic) over the area of cardiac dulness in *pneumopericardium* and *precordial emphysema*. The pericardial sac in the former ordinarily contains fluid as well as air; this becomes evident when the patient sits up, for the lower portion of the abnormally resonant area becomes dull, the fluid following the laws of gravity. (The auscultatory signs will be mentioned later.)

With marked gaseous distention of the intestine or of the stomach, even careful percussion may elicit a tympanitic note over the area of superficial cardiac dulness,

because the vibrations are transmitted to the abdominal contents. But very gentle percussion, in which the pleximeter is applied only by its own weight, and perhaps best with the patient bending forward, will probably enable us to demonstrate the superficial cardiac dulness, and so to differentiate tympanites from the overlapping of the heart by air-containing tissue. A deep cardiac dulness in such cases is difficult, if not impossible, to obtain.

Enlargement of the Superficial and Deep Cardiac Dulness

Enlargement of the Cardiac Dulness from Abnormalities of the Lung Borders.—Both the superficial and the deep cardiac dulness will be increased if the heart push back the anterior lung boundary, or if some anatomic process in the latter (consolidation or atelectasis) add a dull tone of its own to the cardiac dulness. The increase of cardiac dulness does not then depend upon any alteration of the heart's size. Such conditions can be properly interpreted only by carefully considering the entire clinical picture, and by making use of other methods of examination. The most frequent examples are *pulmonary contraction* and the *concentric retraction of the lung*, or an upward dislocation of the diaphragm from marked ascites, meteorism, and the like. (See p. 228.) If the diaphragm be crowded upward, further evidence should be obtained before attributing an increase in the cardiac dulness to an enlargement of the heart.

The increase of the mediastinal fat described by von Hampeln can simulate an enlargement of the heart upward.

Increase of the Cardiac Dulness from Actual Increase of the Size of the Heart or of the Pericardial Contents.—Here the superficial and the deep cardiac dulness are generally increased correspondingly unless an emphysema or adhesions of the pulmonary border complicate the picture (p. 233). In the event of such a complication the superficial cardiac dulness may be much less enlarged than the deep; both may remain small, or may even be absent, on account of the marked covering of the heart. In this way even considerable cardiac enlargement might escape clinical demonstration. The relation of the lungs in other places (inferior pulmonary edge) ordinarily facilitates the diagnosis of these conditions and so prevents the error of deciding that the heart is not enlarged from the lack of an increased cardiac dulness.

The superficial cardiac dulness is very important in demonstrating cardiac enlargement; because the beginner finds it much easier to estimate than the deep dulness; because there is less chance for a subjective variation; and because in decided cardiac enlargement or increase of pericardial contents on account of the considerable lung retraction the entire cardiac dulness frequently becomes superficial.

Actual Enlargement of the Heart.—The heart is pathologically enlarged both by hypertrophy of its walls and by dilatation of its cavities. The extent of the former enlargement must, of course, be limited. The latter will be much greater and more easily recognized. If, while the chambers of a heart retain their normal size, its walls increase about 0.5 cm. in thickness from simple hypertrophy, a difference of only 1 cm. in the width of the heart would result. Now, as a matter of fact, we cannot percuss accurately enough surely to appreciate 1 or 2 cm. increase in cardiac size, nor do we practically ever see post-

mortem as much hypertrophy as 0.5 cm. unless complicated with dilatation. Evidently, then, any enlargement of cardiac dulness which can be demonstrated by percussion must depend upon the dilatation of the cavities, whether there be a coexisting hypertrophy or not.

An appreciable enlargement of cardiac dulness due to a pure hypertrophy of the heart, *i. e.*, one unassociated with dilatation, is, however, sometimes observed in very rare cases, particularly in chronic nephritis. In such cases a diagnosis of pure hypertrophy must be supported by other examination methods (increased force of apex-beat, persistent high-tension pulse, persistently elevated blood-pressure, and accentuated second tone (see below).

The cardiac dulness may be increased in all directions or only in one direction. We naturally attribute a dislocation of the left border

Fig. 138.—Precordial bulging; Enlarged heart and liver; double mitral lesion; percussion boundaries outlined by dotted lines. This picture does not bring out the marked precordial bulging which was very evident in looking at the patient. The width of the cardiac dulness at the nipple-line was 21 cm. (New York City Hospital).

of cardiac dulness to the left to a dilatation of the left ventricle; a dislocation of the right border to the right, to a dilatation of the right ventricle; an increase upward, to a dilatation of the auricles or of the great vessels. But the autopsy table has shown so many exceptions that these conclusions are by no means sure, *e. g.*, marked dilatation of the left ventricle may increase the cardiac dulness upward without there being any dilatation of the auricles or of the great vessels; because if the ventricle be dilated, the oblique position of the heart pushes the dulness upward. The clinical findings might very often induce us to assume a dilatation of the left ventricle when the dulness, as a matter of fact, depends only upon a dilatation of the right ventricle, or vice versa;

or, again, to assume that only one ventricle is enlarged, whereas the autopsy shows that both share equally in the enlargement. The reason of this is that any dilatation of one chamber of the heart must secondarily dislocate the entire heart. Thus, dilatation of the right ventricle increases the dulness not only to the right, but often to the left, pushing the left ventricle in that direction. The position of the mediastinum is a factor in the difference of pressure at either side, *i. e.*, in the two pleural cavities, so that the actual position of a heart with dilated cavities is a complicated result of its own enlargement and of the difference of pressure at the two sides of the mediastinum, which difference is equalized by a dislocation of the mediastinum together with the heart. To make the matter still more complicated, the resistance to

Fig. 139 —Cardiac dulness with dilatation of the right ventricle: dulness is especially increased to the right.

cardiac dislocation is by no means equal in all cases. Great differences are caused by the varying resistance of the mediastinum, by the varying amount of depression of the convexity of the diaphragm, and by individual variations of the prolongations of the pericardium upon the great vessel trunks. The existence of such differences is plainly proved by the different dislocations of the heart from causes acting outside of it (pleural exudates).

It is generally more difficult to demonstrate enlargements of the right heart by percussion than those of the left, because, on account of the notch in the left lung, the left heart is more accessible to percussion than the right, which is covered more completely by lung and by the sternum. Besides, the right ventricle (Fig. 120) rests upon the convexity of the diaphragm, so that if that chamber dilate, the heart

will have the tendency to find the necessary space in the left thoracic cavity because the arch of the diaphragm would present too great a hindrance to its enlarging to the right. Hence a moderate dilatation of the right ventricle often produces only a dislocation of the left cardiac boundary; while it requires a very considerable dilatation of the right ventricle to increase the dulness to the right of the sternum. The most familiar example of this is the displacement of the apex-beat to the left in pure mitral stenosis, where the left ventricle is certainly not dilated. Sometimes, however, the enlargement of the right ventricle (Fig. 139) can be definitely demonstrated to the right. In most of these cases the right auricle takes a prominent share in the enlargement of the right heart, and this is perfectly comprehensible if we remember (see Fig. 120,

Fig. 140.—Cardiac dulness with dilatation of the left ventricle.

p. 218) that the right border of the heart is entirely formed by the right auricle.

So many exceptions make it clear that a diagnosis of the enlargement of a certain cavity cannot be determined from the direction of the increase of cardiac dulness without the general clinical picture and without other methods of examination. The position of the apex-beat, as we shall see below, is perhaps as helpful as anything. Figs. 139 and 140 show typical examples of the position of cardiac dulness in dilatation of the right and of the left ventricle.

Enlargement of the cardiac dulness upward may be due to dilatation of the ventricles, of the auricles, or of the great vessels. Percussion will frequently differentiate the latter two from the former. If the increase of the dulness upward be very pronounced (*i. e.*, in proportion to

the lateral enlargement), or if it assume the form of a projection from, or an appendage to, the ordinary area of cardiac dulness, it is to be referred to dilatation of the auricles or great vessels.

Figs. 141, 142, 143 (examples in point and the representation of the results of percussion in actual cardiac cases) support our contention that such figures are not stereotyped patterns, but correspond to the authentic findings in genuine heart disease. They show quite as characteristic shapes illustrating individual abnormalities as the orthodiagraphic imitation obtained by percussion which this modern method has so suggestively presented as substitutes. (See p. 236 et seq.) The diagnosis of left auricular dilatation and uncovering of the pulmonary artery can be made without question by comparing, in Fig. 141, the striking extent, intensity, and superficiality of the dulness and its

Deep cardiac
dulness

Fig. 141.—Dilatation of the left auricle and left ventricle, with an exposure of the pulmonary artery. in a case of mitral insufficiency.

peculiar projection upward, with the moderate increase of the cardiac dulness to the left, and also by noting the results of palpation appended to the chart. Similarly, Fig. 142 represents an enlargement of the right auricle and Fig. 143, one of the aorta. The three charts represent another important point in cardiac percussion, viz., the relation of the superficial to the deep dulness in enlargement of the heart. Figs. 139 and 140 show an enlargement outward, with the borders of superficial and deep dulness practically parallel to each other, so that, as under normal conditions, the superficial dulness is entirely surrounded (except below) by a strip of relative dulness. This illustrates a reasonably frequent occurrence; but quite as often with pronounced enlargement of the heart the relations represented in Fig. 141 appear. Here, at many points (in this figure above and near the apex-beat) or throughout

the entire extent of the heart the borders of the superficial and of the deep dulness merge so that there is only a superficial dulness. It results from the enlarged heart crowding back the lung edges, so that the entire heart lies directly against the thorax, and naturally furnishes only a superficial dulness. In Fig. 141 the left auricle has pushed the border of the lung so far aside that this chamber and the pulmonary artery both lie close against the chest-wall; while the less markedly dilated left ventricle is still partly covered by the lung; hence, outside of the superficial dulness, a slight relative or deep dulness exists.

Fig. 142 represents a marked dilatation of the right auricle and right ventricle in tricuspid insufficiency. Here again the lungs are pushed so far aside that the entire dulness is superficial, and the left edge and

Deep cardiac
dulness

Fig. 142.—Dilatation of the right auricle and right ventricle in a case of tricuspid insufficiency.

the apex of the heart lie perfectly free. Above and to the left a small zone of relative dulness remains.

It can be seen in this figure, just as in Fig. 139, that the superficial dulness includes all the lower part of the sternum. Hence the dulness can be well defined above, although normally it is difficult to determine by percussion the solid from the air-containing parts (see p. 224) beneath the sternum.

From the bulging of the cardiac dulness upward, as in Figs. 141 and 142, the percussion results alone are not always sufficient to decide whether the auricles or the great arteries are responsible for the enlargement. The other conditions, especially the kind of pulsation over the area, will then assist in settling the diagnosis. (See Palpation and Inspection of the Heart Region.) The percussion results in Fig. 143 are, however, sufficiently characteristic to justify the diagnosis of a dilatation of the aorta.

Fluid Effusion in the Pericardium.—When fluid accumulates in the pericardium, whether as a result of general dropsy or of inflammation of the serous membrane, its cavity becomes more and more distended and the edges of the lung are pushed aside, just as by the enlarged heart. If the pericardium lie against the thorax wall, percussion elicits a superficial (often absolute) dulness; while where it is still covered by the lungs the dulness will only be relative, and the superficial and deep dulness will run concentrically. If the distention of the pericardium be very marked, the lungs will be pushed aside and the entire dulness may be superficial. The form and the position of the cardiac dulness enlarged by pericardial effusions are, from the anatomic conditions, generally very characteristic. (See the subsequent charts in the section, *Diagnosis of the Different Valvular Lesions.*) The specific

Fig. 143.—Cardiac percussion results in a case of diffuse dilatation of the aorta from aortic insufficiency; dilatation of the left ventricle.

gravity of the effusion is always less than that of the heart itself; therefore, with accumulating effusions, *i. e.*, as soon as the lateral portions of the pericardium are filled, the fluid will occupy the upper portion of the cavity, and the heart itself the lower. Even relatively slight effusions will increase the cardiac dulness in the dorsal decubitus, because the fluid is then collected against the anterior thoracic wall. If the patient be slightly raised from the recumbent posture, the fluid first collects at the superior bulging of the pericardium, in the neighborhood of the great vascular trunks, beneath the upper end of the sternum, and there pushes the lungs aside. Therefore, quite early in pericardial effusions the cardiac dulness reaches high up under the sternum or in its neighborhood, and assumes a characteristic triangular shape, with a blunt apex above and a broad base below. This triangular form is nothing more than the expression of the shape

of the portion of the dilated pericardium which lies against the anterior thoracic wall, and since the pericardium is wider at its diaphragmatic portion than at the great vessels, the lungs are pushed further aside at the lower than at the upper part. Pericardial distention shows especially plainly at the so-called cardiohepatic angle (Fig. 136), for the lung is very early pushed aside to the right of the sternum, and so changes this angle, normally about 90° or slightly more, to a much more obtuse angle.¹ An erect posture makes the dulness broader and somewhat lower than in the dorsal decubitus (if the effusion be larger), because the fluid, following gravity, flows further forward. Adhesions of the pericardium may prevent the application of any rules for determining the shape of the pericardial dulness.

Under normal conditions (see p. 240) a depression of the cardiac dulness occurs in the upright as compared with the recumbent posture; and the same depression of the upper borders of dulness during the sitting posture has been observed in actual enlargement of the heart from valvular lesions. Therefore we cannot always diagnose a pericardial effusion from the alteration in dulness noted above in the change of posture from lying to sitting. The action of gravity upon the enlarged heart may depress the diaphragm and so cause a lower position, or it may be that more venous blood is retained in the lower half of the body in the vertical position, so that the auricles are not so completely filled. But if the erect posture produce a pronounced broadening of the lower part of the dulness, it is certainly more suggestive of a pericardial effusion than if it produce a mere depression of its upper border.

DISLOCATION OF THE HEART DULNESS IN TOTO

The position of the diaphragm varies with the age and the sex, and is responsible for variations in the situation of the heart which are permanent for the individual. Orthodiagraphic examinations (see p. 229) should be compared in this connection.

Otherwise the position of the movable organs of the thoracic and abdominal cavities at any given moment is the result of the muscular and elastic forces pushing or pulling them on every side and of the limitations to their mobility. The position of the heart is essentially due to the position of equilibrium in which the mediastinum is held between the two pleural cavities and to the position of the diaphragm. Any change of the diaphragmatic position or any disturbance of the equality of pressure between the two pleural cavities will produce a dislocation of the heart.

The pathologic dislocation of the heart contingent upon a dislocation of the diaphragm will be especially marked if the latter develop slowly, because a gradual stretching overcomes the resistance which makes a dislocation of that part of the diaphragm upon which the heart rests so difficult (fixation of the central tendon by the mediastinum, esophagus, aorta). *Meteorism, ascites, and voluminous abdominal tumors* push the heart upward; *emphysema* and *collections of fluid or air* in the pleural cavities push it downward.

A pathologic dislocation of the heart to the side ensues if the negative pressure in one pleural cavity become less markedly negative, or if it become positive. The heart will be pushed toward the side where the absolute pressure is less, *e. g.*, large collections of air or fluid in one pleural cavity dislocate the heart to the opposite side. Thoracentesis generally proves that an effusion which dislocates the heart to any

¹[Rotch has emphasized the value of this sign in the diagnosis of pericardial effusions in children.—Ed.]

extent is under positive pressure; nevertheless, an effusion under negative pressure would exert a similar dislocating action, for such an action does not depend upon the absolute height of the pressure, but upon the difference between the pressures affecting the two sides of the mediastinum. The heart is merely pushed to one side until this difference in pressure is equalized. The practical importance of this fact, that even a fluid effusion under negative pressure may dislocate the heart, is the warning it gives us always to avoid the risk of introducing air into a chest by aspiration, whether the heart be dislocated or not.

Pathologic dislocation of the heart may occur not only when the negative pressure on one side becomes less negative or becomes positive, but also when upon one side of the mediastinum it becomes still more markedly negative. Here the action is more that of suction than of pressure, and is observed in pleural effusions which have led to a retraction of the lungs. As the exudate becomes absorbed, the heart is drawn over *toward the affected side* to fill the empty space. In fresh pleurisy the heart is pushed *toward the healthy side*. In retraction of the lung from other causes than pleurisy, *e. g.*, from interstitial pneumonia or tuberculosis, the heart is likewise dislocated to the affected side. It may remain there permanently from continued tugging, or it may gradually return to its normal position from a gradual distention of the lungs.

There is no law to determine how deformities of the thorax will dislocate the cardiac dulness.

The cardiac dulness in *situs inversus* and in *dextrocardia* occupies the right side, forming a sort of reflected image, symmetric to its normal form and position.

By starting from the normal relations we can easily understand the form and position of a dislocated cardiac dulness. Slight dislocations (from pleural effusions, etc.) produce only a lateral displacement, while marked dislocations occasion both a lateral and a pendulum movement. On account of the normal oblique position of the heart, such a pendulum movement probably occurs more readily in dislocations to the left; whereas, on account of the resistance of the central tendon of the diaphragm, a similar pendulum dislocation to the right requires much more force.¹ The results of pathologic findings and the experiments of Ferber¹ finally settled the much disputed pendulum movement of the dislocated heart.

If the heart be dislocated by a pleural effusion, the dulness of the latter usually merges with the cardiac dulness so that only the borders of the other side of the heart are demonstrable by percussion. If the heart be dislocated to the left, its left edge will assume the same position as in left-sided cardiac dilatation. If retraction of the right lung or a left-sided accumulation of air or fluid crowd the heart considerably to the right, the right cardiac boundary and even the apex-beat (exactly as in *dextrocardia*) may be found in the neighborhood of the right mammillary line or even still further outside. Both superficial and deep cardiac dulness will be found to the right of the sternum; the former will merge into the liver dulness, and the latter will run around the superficial dulness, in the shape of a concentric border, from above and to the right. We can differentiate the result from *dextrocardia* either

¹ Die physikalischen Symptome der Pleuritis exsudativa, Habilitationsschrift, Marburg, Elwert, 1875.

by the signs of right pulmonary retraction, by the pleural dulness which occupies the place of the normal heart dulness, or by the signs of a left pneumothorax; from *situs inversus*, by the normal right-sided position of the liver.

Fig. 147 shows a large left-sided pleural exudate dislocating the cardiac dulness to the right; Fig. 149, a right-sided pyopneumothorax pushing the cardiac dulness to the left. From these figures it can be seen that in dislocation of the heart the lung edges may be so completely pushed aside as to make the entire cardiac dulness superficial, as in enlargements of the heart (see p. 242) and pericardial effusions. (See p. 248.)

If the heart be pushed upward by abdominal distention, the cardiac dulness not only lies higher, but also appears larger, *i. e.*, broader than normal. This is partly due to the retraction of the lung edges away from the heart in consequence of the limitation of space in the thorax. (See pp. 228, and 242.) The heart dulness may even be twisted by a sort of pendulum movement into a horizontal position, because the apex of the heart, which lies upon the movable portion of the diaphragm, is lifted up to the level of, or even higher than, the base.

TOPOGRAPHIC PERCUSSION OF THE LIVER

NORMAL LIVER DULNESS

Clinicians have often attempted to determine a superficial and a deep dulness for the liver just as for the heart, *i. e.*, to bound the anterior surface lying directly against the thoracic and abdominal wall, and to estimate the height to which the liver in the dome of the diaphragm rises into the thorax. The latter determination would be of very little value even if it were possible. The highest point of the liver lies far removed from the anterior thoracic wall; and in large persons with well-developed chests it is beyond the range of the percussion blow. Again, although we can obtain a relative dulness (a diminution of the fulness of the tone) above the lung-liver boundary corresponding to the wedge-shaped form of the lower edge of the lung, yet the upper limit of this dulness will almost always be lower than the highest point of the liver. But, as stated above, the estimation of the highest point of the liver is of little value. The liver is applied closely to the diaphragm, and so the upper liver boundary merely coincides with the position of the diaphragm, and we can determine that accurately enough by estimating the position of the upper border of the heart, the lung-liver boundary, and the liver edge. If the diaphragm be high, the lung-liver boundary and the liver edge are always high. If the diaphragm be low, the reverse is true. The lower liver boundary, which is generally easy to determine by percussion, usually shows whether the organ is increased or diminished in size. An enlargement of the liver pushes the lower liver edge correspondingly downward; except, though rarely, when the muscular resistance of the diaphragm is diminished, *e. g.*, with circumscribed tumors of the upper liver surface, *abscesses*, or *echinococcus cysts*. Even here the estimation of the so-called "relative liver dulness" is apt to be so unreliable as to be of little value, for the superficial lung-liver boundary is probably always somewhat elevated by such a growth.

Ordinarily, therefore, we are contented with estimating by percussion the part of the liver applied to the abdominal wall and situated beneath the edge of the lung. Under favorable circumstances we can map out a superficial dulness such as is pictured in Fig. 125. At the sharp edge of the liver this dulness is naturally so slight that only very light percussion appreciates the dulled note, while stronger percussion sets the underlying intestines in vibration. In the same way very light percussion is essential near the lung, as is naturally requisite in determining any superficial border, for otherwise the resonant tone of the adjoining lung tissue obscures the dulness and renders an exact definition impossible. Stronger percussion, however, brings out very clearly the superficial liver dulness higher up, corresponding to the thickness of the layer of the liver percussed. The upper borders of the superficial liver dulness coincide with the lower borders of pulmonary resonance. They can be plainly demonstrated from the front to the back. To the left of the median line, the superficial hepatic dulness merges with the superficial cardiac dulness at the fifth to the sixth rib between the left parasternal and mammillary lines (Fig. 136, p. 234). The possibility of distinguishing an inferior border of the superficial or deep cardiac dulness depends upon how far the left lobe of the liver reaches to the left. (See p. 234.) In the median line the inferior border of the superficial hepatic dulness lies halfway between the navel and the base of the xiphoid process, sometimes even higher. In the right mammillary line it reaches the edge of the ribs or projects slightly below them, and it lies upon the tenth rib at the right middle axillary line. All these measurements refer to patients who are breathing quietly and in the recumbent posture. The inferior edge of the liver behind cannot usually be plainly demonstrated on account of the thickness of the muscle layer.

The author protests against making statements about the absolute height of the liver dulness because no general value can as yet be attached to such measurements; but in concrete cases the vertical diameters of the liver dulness at the different arbitrary lines should be measured in order to recognize any changes in the liver size during the observation of the same case.

ACTIVE AND PASSIVE MOBILITY OF THE LIVER DULNESS

The liver dulness also possesses an active mobility with respiration, and a passive mobility with an alteration of the patient's position. The active and passive mobility of the upper edge of the superficial liver dulness coincides with the corresponding mobility of the pulmonary border (p. 225 et seq.). The active mobility of the lower liver border corresponds to the respiratory mobility of the dome of the diaphragm, and is much less than that of the pulmonary border. When a patient lies upon his left side, the passive mobility of the lower liver edge is shown by a depression of the right lobe. When he lies upon the right side, the reverse occurs (rotation of the liver about a sagittal axis). The liver is more difficult to percuss in the sitting or standing posture, on account of the increased tension of the abdominal walls. The lower liver border is occasionally elevated in these positions, probably because the increased intra-abdominal pressure pushes the liver to some extent upward, and thereby rotated about a frontal axis, it is turned up on edge. In this case the pulmonary hepatic boundaries are elevated somewhat in the erect posture. If the abdominal walls be lax, the weight of the liver produces the reverse effect. (See Lung-liver Boundary.)

PATHOLOGIC DISLOCATIONS AND GROSS CHANGES IN THE LIVER DULNESS

In "situs inversus" the liver lies in the left upper abdomen, symmetric with its normal position. Its dulness corresponds to the reversed position. Free air in the abdominal cavity nearly obliterates the liver dulness, because the air will be collected at the highest points. (See the Section upon Comparative Percussion of the Abdomen.)

Changes of the Upper Border of the Superficial Liver Dulness.—The upper border apparently lies higher than normal if a pathologic dulness from the thoracic organs (pleural effusion or lung consolidation) be superimposed upon the liver dulness. It is, therefore, necessary to resort to other methods of examination to determine whether it is a genuine high liver dulness or a normal liver dulness plus a pathologic pulmonary or pleural dulness (see below under Comparative Percussion). The existence of definite symptoms of a pleural effusion or a pulmonary consolidation will, of course, be of value.

The upper border will be higher if the liver be pushed upward in toto, *e. g.*, by increased abdominal tension. In this case the liver will ordinarily be rotated about a frontal axis, so that its inferior edge is elevated out of proportion to the lung-liver boundary, and the vertical breadth of the liver dulness appears abbreviated (angular position of the liver). If, at the same time, the liver be enlarged, despite its being canted upward, the lower edge may stand at its normal place or even lower.

Pulmonary retraction will also cause a higher position of the lung-liver boundaries.

A mere diffuse enlargement of the liver without marked increase of the intra-abdominal pressure, *i. e.*, without the liver being pushed upward, will not ordinarily cause an elevation of the lung-liver boundaries, because the organ will naturally enlarge in the direction of the least resistance (downward), and not against the diaphragm. With increased abdominal tension or if such an enlargement of the liver be excessive and occur so rapidly that its ligaments are not quickly enough stretched, a marked increase upward will result, *e. g.*, most frequently in unequal enlargements of the upper surface of the liver, which cause a localized pressure (tumors, echinococcus cysts, and abscess of the convexity). In most of these cases, however, the lower edge of the liver will also be pushed downward. Subphrenic abscesses produce practically identical percussion results with those obtained in tumors of the convexity.

Emphysema, either by crowding the diaphragm in toto downward or by filling the pleural sinus more completely with lung, will depress the upper border of the superficial liver dulness to a variable degree, depending upon which of these possibilities is present. *Pneumothorax* effects a similar result. Lessening of the intra-abdominal pressure, and exceptionally *enteroptosis*, will also depress the upper border of the superficial liver dulness.

Changes in the Lower Border of the Superficial Liver Dulness.—We have discussed some of these in the preceding section. They depend either upon a dislocation of the liver, a change in its size, or upon an association of these conditions. A careful attention to the entire clinical picture will differentiate these different conditions, *e. g.*, the etiologic and the accompanying relations (stasis); a palpatory appreciation of alterations in the consistence (cirrhosis, carcinoma); or

the absence of a dislocating cause. Conversely, the existence of a cause for dislocation (pleural effusion, abdominal distention, enteroptosis) suggests the possibility of dislocation; the existence of an enlargement or diminution in size, with careful attention to the other symptoms, suggests its improbability. All these are frequently such difficult problems in diagnosis that no constantly applicable rules can be given.

If the dislocating cause affect the entire upper or lower surface evenly, the lower edge of the liver will be pushed upward or downward as a whole, *i. e.*, symmetric and parallel to its former position (meteorism, ascites, emphysema). If, on the contrary, the pressure act unevenly, the organ will, by virtue of its attachments, be dislocated in an asymmetric fashion.

Accumulations of air or fluid in the right pleural cavity exceptionally rotate the liver about a sagittal axis. Conversely, a left pleuritic or left pericardial effusion will sometimes depress the left half of the liver. Similarly, though in a reversed way, a one-sided pulmonary retraction will elevate the liver.

Solid masses beneath the liver (packed intestines, tumors of the omentum, of the colon, of the stomach, and the like) may increase the liver dulness downward. Palpation or a carefully repeated examination generally discloses the true condition.

Conversely, intestines distended with air, overlying the liver and hiding part of it, may simulate a high position of the liver edge.

TOPOGRAPHIC PERCUSSION OF THE SPLEEN

NORMAL SPLENIC DULNESS: SEMILUNAR (TRAUBE'S) SPACE

The spleen lies in the left hypochondrium, between the ninth and the eleventh ribs (Figs. 121 and 122). Its long diameter ordinarily lies beneath the tenth rib. Its upper pole is situated only a few centimeters from the spinal column. Its lower pole reaches only to the middle or, at most, to the anterior axillary line. In relation to the course of the ribs, the long axis of the organ runs from behind and above forward and downward. The posterior upper third of the spleen lies hidden under the edge of the lung. The anterior and lower two-thirds ordinarily lie against the thoracic wall unless, as very frequently happens, intestines have been pushed in between the latter and the spleen.

Percussion can differentiate only that portion of the spleen which is uncovered by lung. Hence, it merely estimates a superficial dulness which can be accurately determined only by very light percussion. (See p. 211.)

To map out the free part of the spleen as perfectly as possible by means of percussion the patient should be sitting, standing, or lying upon the right side (the so-called lateral or oblique positions), because in the directly recumbent position the posterior portions of the spleen are not accessible to percussion. The lateral or oblique position has the advantage that the dulness due to ascites or to the contents of a well-filled stomach is shifted and so does not simulate the dulness of an enlarged spleen.

The normal splenic dulness in the sitting or standing posture is pictured in Fig. 126. The upper boundary of the dulness corresponds to that portion of the lung edge which intersects the eighth and ninth

ribs, and runs from the middle to the posterior axillary line. The anterior border of the dulness rarely reaches the anterior axillary line; in adults it is about 5 cm. above the costal margin. The dulness reaches as low as the eleventh rib. Measured in the long axis of the body, the height of the dulness varies between 5 and 6 cm. Posteriorly the splenic dulness merges into that of the lumbar region, due to the thick layers of muscles, not to the kidneys. (See p. 256 et seq.)

In changing from the sitting or standing to the recumbent posture, the splenic dulness is but slightly dislocated and then inconstantly either upward or downward as a whole. The cause of this displacement has been discussed upon p. 226 (passive mobility of the lung borders). (See p. 226.) The anterior boundary then usually remains the same. The splenic dulness is only slightly dislocated forward and downward in the oblique and lateral postures, because, although the left lung then assumes a deeper position, at the same time more of the upper part of the spleen is covered by the lung. A splenic dulness which projects beyond the anterior axillary line, even in the oblique and lateral posture, is abnormal.

The beginner should practise splenic percussion upon patients first in one position, then in another, in order to control his results.

It is impossible to map out the portion of the spleen lying above the edge of the lung, *i. e.*, to determine a deep splenic dulness. The spleen is a comparatively small organ, covered outside by the lung, and inside in contact with the stomach and intestines, so that a percussion stroke strong enough to penetrate the lung would set the tympanitic stomach into vibration. Besides, the differentiation of that part of the spleen covered by the lung has no practical value, because, just as in the case of the liver, any alterations can be easily recognized in the accessible part. (See p. 251.)

Percussion of the spleen is frequently not so simple as the above description would indicate. The spleen may be abnormally broad behind, or may lie abnormally high, so that it practically escapes percussion, though its size be within physiologic limits. With meteorism, especially when the distended intestines push the spleen upward and backward or crowd between the spleen and the thoracic wall, the vibration of such large air-containing cavities may make it almost impossible to differentiate so thin a solid organ as the spleen. Again, solid or fluid stomach or intestinal contents sometimes simulate a splenic dulness. The right lateral or oblique position will generally prevent confusion due to stomach-contents, and a later examination will show the true state of affairs in regard to the intestinal contents. Despite every care, however, repeated examinations, varying strengths of percussion, changes of patient's position, it must be acknowledged that palpation is very much more trustworthy than the percussion of this organ.

Between the splenic dulness and the left limit of the liver dulness there is normally a tympanitic area due to the stomach or intestines. This space is bounded above by the lung border, below by the free costal margin, and is called the semilunar or Traube's space. It is important in the diagnosis of left-sided pleuritic exudations (Figs. 125, 126, and 146). Percussion cannot always differentiate this space above from the lung; but then a boundary line can always be constructed corresponding to the edge of the right lung.

GROSS PATHOLOGIC CHANGES AND DISLOCATIONS OF THE SPLENIC DULNESS

Enlargement of the spleen is ordinarily evident by an increase in the splenic dulness forward and downward (Fig. 144). If the splenic dulness project forward beyond the anterior axillary line, or if its vertical extent in adults measure more than 7 cm., the spleen may be considered increased in size.

Diminution or even a complete disappearance of the splenic dulness happens frequently enough in perfectly healthy men with normal spleens. It would be impossible to distinguish such a condition from a pathologic diminution, and the latter is clinically unimportant.

Pathologic dislocations of the spleen are of slight clinical importance. They are usually difficult to demonstrate. Although pleural effusions, meteorism, and tumors may dislocate the spleen, percussion will rarely be of much help, because

Fig. 144.—The splenic dulness in different grades of splenic enlargement (a, b, c, d).

either another dulness occupies that of the spleen, or else there is a resonant note (meteorism). Pronounced ascites pushes the spleen under the left lung so that it cannot be demonstrated.

With a marked dilatation of the stomach or enteroptosis the spleen is sometimes dragged downward and forward by the pull of ligamentum gastrosplenicum. It will then be more accessible than normally to percussion and palpation. (See later, Examination of the Stomach.)

Large pleural effusions occasioning a dulness in Traube's space, as well as enlargements of the liver, may cause the hepatic and splenic dulness to merge. (See Fig. 146.) Under these circumstances percussion may not detect even marked enlargements of the spleen.

TOPOGRAPHIC PERCUSSION OF THE KIDNEYS

The anatomic position of the kidneys (Figs. 121 and 122) precludes the possibility of mapping out their boundaries by percussion. Their deep

position prevents percussion from in front, and the thick layers of muscles behind cause a dulness which such a thin structure as a kidney could not increase. If we percuss a patient whose kidney has been removed, we can demonstrate the same vertical boundary of dulness as in a patient with an intact kidney. It corresponds to the outer edge of the sacrospinal muscles and has nothing to do with the kidney. Large renal tumors afford an intense dulness in the loins, projecting far beyond the boundaries of the sacrospinal muscles. If the tumor has pushed the other abdominal viscera aside and lies against the abdominal wall, it can be demonstrated from in front. Here it is of special diagnostic importance to demonstrate by percussion that the colon is anterior to the kidney (see below). Palpation is, however, far more important than percussion in this instance, as in the diagnosis of all other abdominal tumors.

TOPOGRAPHIC PERCUSSION OF HOLLOW ABDOMINAL VISCERA

(See also section upon Examination of the Stomach.)

Percussion is of no value for distinguishing one of these organs from the other, except under certain quite well-recognized conditions, viz., where the stomach or separate sections of the intestines are filled with air, fluid or solid contents. And then only superficial boundaries (*i. e.*, with light percussion) can be accurately estimated, because stronger percussion transmits the vibrations in all directions to an indeterminable and often to a considerable distance. Even superficial percussion is quite untrustworthy, because physiologically the position of the stomach and intestines varies considerably; because their superficial boundaries are rarely sharp; and because, although over different portions of the intestines the tympanitic tone varies in intensity and pitch, it is impossible to differentiate one region from the other. We can usually distinguish the swollen stomach or the distended colon from the small intestines by ordinary percussion. If this be not possible, the stick-pleximeter percussion or the auscultatory percussion (see p. 205) will differentiate them, provided there is enough increase in tension to produce a metallic resonance over the air-containing viscera. Both these methods of examination elicit at the edges of the organs either a sharp rise in the pitch of the metallic resonance or a sudden cessation of the resonance. However, every spot over a hollow organ does not necessarily give the same pitch of metallic resonance. Metallic resonance over an air-cavity may be present or lacking; and, again, its pitch may differ over different parts of the organ, especially if the latter be distended. If we trace the course of the colon distended with gas by means of the stick-pleximeter percussion, we can often appreciate entire scales of metallic resonance. Different pitches may be present even over the stomach. This is easily explained by the fact that a metallic resonance (see p. 207) is caused by the air in a hollow organ vibrating so as to give high, discordant overtones. In an irregularly shaped organ these overtones will naturally vary according to the spot percussed, and according to the direction of the blow. Hence, the value of this examination method must be limited, although we may make it easier by distending the stomach or colon with air. (See Palpation of the Abdomen and Examination of the Stomach.)

The demonstration by percussion of the tympanitic colon anterior to

a kidney tumor is very valuable for diagnosis (Fig. 167). The topography of this condition is described under Palpation of the Kidneys. It is safer to percuss both before and after distending the colon with [water and then with.—ED.] air.

Inspection and palpation (especially after distending the stomach, see p. 424) generally furnish better evidence of the extent, position, and condition of the stomach and intestines than percussion. (See here special section, Examination of the Stomach.)

TOPOGRAPHIC PERCUSSION OF THE BLADDER AND OF THE UTERUS

The bladder when empty lies well hidden behind the symphysis pubis. When filled it ascends, even reaching, in cases of urinary retention, above the navel. As it rises it pushes the intestines aside and lies against the abdominal wall in the form of a vertically placed oval tumor, furnishing to light percussion an intense dulness, which corresponds pretty accurately to its extent and shape. If not very markedly distended and if some loops of intestines lie between it and the abdominal wall, part of the dulness may be deep (plainer to strong percussion), or there may even be no dulness present.

According to Müller's investigations, a bladder must contain between 500 and 600 c.c. before it will produce an appreciable dulness in normally developed women, and 360 to 500 c.c. in men.¹ If the rectum be distended, the bladder dulness projects somewhat more to the right. In lateral positions it is depressed to the deeper side, sinking at the same time somewhat into the depth of the pelvis, and so appearing smaller.

The condition of the bladder can be determined more accurately by palpation than by percussion unless the abdominal walls are very thick or rigid.

The pregnant or pathologically enlarged uterus acts like the bladder to percussion, and can be distinguished from it only by careful attention to other clinical conditions, by determination of the consistence, by means of palpation, by vaginal examination, and by catheterization.

COMPARATIVE PERCUSSION

Topographic percussion, as we have seen, furnishes us with conclusions as to borders, *i. e.*, as to the size and position of organs. Comparative percussion is concerned with the qualitative changes of the percussion-note over one and the same organ, and the conclusions to be drawn from such changes in regard to the condition of the organ and its surroundings. It is so designated because we compare the note over a certain spot of the body with the normal note over this spot, or with the note over adjacent or symmetrically placed (normal) areas of the same organ or of the same part of the body. It is a matter of choice whether we determine the relations of dulness of fluid effusions in the serous cavities by topographic or, as is done here, by comparative, percussion. The solid organs, however, belong exclusively to the domain of topographic percussion because it can only bound them (*i. e.*, determine their size, not their structure), and for this purpose topographic percussion is all that is essential. But with the air-containing organs of the abdomen, and more especially those of the thorax, the lungs,

¹ Berlin. klin. Woch., 1895, No. 13, p. 278.

we may determine countless qualitative modifications of the percussion-note which will furnish us most important information about pathologic changes at their surface or in their interior.

COMPARATIVE PERCUSSION OF THE THORAX

The ordinary note over the lung is resonant, loud, not tympanitic. The resonance or loudness varies with the thickness of the covering, and is also influenced by the adjacent organs (heart, liver, etc.). Beneath thick muscles or fat, *e. g.*, over the scapula and over the female breast, the percussion-note is less resonant than at other places. The intense dulness of the pulmonary tone in such spots can be modified only by very vigorous percussion. On the upper end of the sternum and the immediately adjacent areas the note is less resonant than over the sides of the thorax. This is due partly to the anterior mediastinum and its great vessels, and partly to the sternum supported by the unyielding framework of the upper ribs. (See p. 237.) Again, the pulmonary tone is less resonant (see p. 212 et seq., pp. 235, 250) over areas where the pulmonary tissue is thin, *e. g.*, the note over the apices or borders is normally duller than that over the intermediate, more voluminous portions of the lung. The examiner's ear gradually accustoms itself to these physiologic differences, so that they are instinctively appreciated. Marked convexity of the thoracic wall will cause a certain dulness, *e. g.*, in kyphosis and scoliosis. If we percuss upon a markedly convex spot of the thorax, a part of the percussion force is lost, because such a place yields so little; whereas a flat section of a rib oscillates to percussion in the direction of its greatest elasticity and so offers the best conditions for the transformation of the percussion stroke into vibrations. We must, therefore, be careful in drawing conclusions from the notes obtained over kyphoscoliotic chests, and physiologically as well, the resonance of the pulmonary tone varies decidedly according to the different configurations of the thorax.

Every structural change of the lung itself has an important influence upon the character of the pulmonary note, which may become abnormally resonant, tympanitic, or more or less dulled. The change can be appreciated by comparing the note with that over either symmetric or neighboring normal areas. Wherever the changes in the note include an entire lung, the beginner must compare the note with that of a healthy person. To the skilled these variations from the normal are easily appreciated without such comparison.

OCCURRENCE OF A DULLED NOTE WITHIN THE LUNG BOUNDARIES

In order not to overlook slight dulness, it is always a good rule to utilize percussion of varying strengths. To make clear the importance of this precaution, it is necessary to enumerate the different anatomic possibilities which can produce a dulness in the lung tone.

Whenever the range of the percussion blow includes a smaller amount of air-containing lung tissue, or an area containing less air than normally, the tone will be dulled (p. 216 et seq.). This may be caused:

1. By the interposition of airless material between the lung and the thoracic wall: exudations, adhesions, tumors (Fig. 145, I).

2. By diminution or absence of air in the lung parenchyma itself,

e.g., in (partial or complete) *atelectasis* (collapse of the alveoli), from compression or from closure of the bronchi with consequent resorption of the air; in *pneumonia*, from the (partial or complete) filling of the alveoli with an airless inflammatory exudate; in *new-growths*, from the tumor tissue taking (to a greater or less extent) the place of the lung

I. Pleural exudation: A, Sphere of action of light percussion; B, compressed lung; C, pleural exudate.

II. Superficial infiltration area: A, Sphere of action of light percussion; B, B, air-containing lung tissue; C, consolidated lung tissue.

III. Disseminated small areas of consolidation: a, Sphere of action of strong (deep), b, of light, percussion; A, A, air-containing lung tissue, B, small consolidated areas.

IV. Larger areas of consolidation lying deeper: a, Sphere of action of light, b, of strong (deep), percussion; A, A, air-containing lung tissue; B, consolidated lung tissue.

Fig. 145 The different varieties (i. e., methods of origin) of dulness of the lung tone. Diagrammatic frontal section through the thorax: I, Pleural exudate; II, III, IV, pulmonary consolidation.

tissue. These changes may occur in large areas which reach the surface of the lung (Fig. 145, II); in small scattered areas (lobular), partly at the surface, partly separated from it by lung tissue still containing air (Fig. 145, III); or, finally, in still larger areas situated in the depths of the lung (Fig. 145, IV). Each of these cases will furnish different percussion results.

If we percuss vigorously at *b* (Fig. 145, I), provided the exudate is not too thick, the lung can be so strongly vibrated that the dulness will be completely overlooked. To differentiate such a dulness as sharply as possible from the surroundings we should here percuss as lightly as possible. The same holds good for the condition represented in Fig. 94, II. The dulness is superficial in both instances, and can be best defined by regulating the range of the percussion blow so that the volume vibrated lie within the solid tissue, as in Fig. 145, II.

In Fig. 145, III, no very marked dulness can be evoked either by light (*b*) or by strong deep (*a*) percussion; both types will furnish only a slight dulness, because air-containing tissue will still be vibrated. The results of light or strong percussion will vary with the position, in relation to the surface, of the consolidation. If the consolidation as a whole be not very extensive, light percussion will bring out the dulness more plainly, because less air-containing tissue in the interior will be set in vibration.

Light percussion (range *a*) will demonstrate nothing with a larger, deeply placed area, as in Fig. 145, IV; but strong percussion (range *b*) will demonstrate a relative dulness.

Of course, we do not know beforehand whether there is any dulness, or if so, what kind of dulness; therefore it is always advisable to employ successively different strengths of percussion. Then we can decide as to the cause, relative position of the dulness (deep or superficial).

It is not to be expected that percussion can demonstrate every small area of consolidation. In fact, experience teaches us that isolated areas of consolidation, even though superficially located, to be appreciated must have a surface extent of at least a *few square centimeters*. If they lie more deeply, they must naturally be larger. But there are no generally applicable rules. For instance, multiple areas, if scattered thickly enough, need not be nearly so large as single areas to impair the resonance, *e. g.*, a lung richly studded with miliary tubercles will sometimes give a relatively dulled note. At other times, on the contrary, even thickly spread small areas will cause no dulness. The author has watched cases where the pulmonary resonance was absolutely normal during life, and yet at autopsy the lungs were everywhere infiltrated with sarcomatous nodules the size of nuts. There are many other important factors in this connection besides the amount of air contained in the lungs. For example, a relaxation of the lung tissue adjacent to solid areas will make the note more resonant than normal (see p. 271), and this hyperresonance may overbalance the dulness from disseminated tumor nodules or inflammatory consolidations.

In most cases other methods of examination must be resorted to in order to determine the cause of dulness. The most important characteristics of the different kinds of dulness of the lung tone will be mentioned in the following sections.

Pleuritic Dulness

Early in its formation a pleuritic effusion occasions a dulness in the lower posterior part of the thorax. This gradually rises higher, and pushes further forward, the boundary line running downward and forward (Figs. 146, 147, I, II). If the effusion increase still more, the

dulness extends forward, until finally the greater part of that side of the chest is dull, except that in the upper portions a slightly resonant note can be elicited. Exceptionally, the upper border of dulness may run circularly around the thorax instead of bowing down toward the front.

Why this line of dulness, which represents the actual position of the border of the exudate, is oblique has been a mooted question. The ordinary supposition is that the force of gravity determines the position of the exudate, and that the characteristic inclination is essentially produced by the patient's position during its development, and then fixed by encapsulation. If, then, a patient during the entire course of a slowly developing exudate be walking about, we should naturally suppose that the fluid would assume a horizontal level due to gravity. As in most cases, however, patients remain in bed with the head slightly raised, the line running downward and forward would correspond to a horizontal one for them. But this theory will not hold, for even if patients do walk about during the formation of an exudate, the same inclined line is almost always found. Some other cause must, therefore, be responsible for this peculiarity. The author considers that the following supposition is probably correct. Normally, the surface of the lungs is kept applied to the costal pleura by the difference between the air-pressure within the bronchi and the power of retraction or elasticity of the lungs. Now, it is physically impossible that the elasticity of so irregularly shaped an organ as the lung should be the same at all points of the surface. And wherever the retraction power of the lung is stronger, there it is that more of the intrabronchial air-pressure will be borne, because the physical force preventing the mechanic separation of the layers of the pleura is less. The posterior, more voluminous parts of the lungs undoubtedly possess the strongest retraction power, so that the exudate finds there the least resistance to its formation and accumulation. Thus, the boundary line bends downward and forward. In favor of this supposition is the fact that the exudate is not only higher, but also thicker behind.

As an argument against this hypothesis it has been stated that in hydrothorax the level of the fluid sometimes assumes a horizontal position, in the sitting and erect postures encircling the chest horizontally, while in the recumbent posture it disappears in front. The influence of gravity, however, in large dropsical accumulations must be very marked, so that the comparison is scarcely justifiable; but a very slight hydrothorax is, on the contrary, quite analogous to an exudate. The former exhibits the same line of dulness inclining downward from behind forward in the erect posture. (See p. 267.) With a freely movable fluid, not restricted by adhesions, one would naturally suppose that it would follow the law of gravity. Since it does not, there must be some power at work to fix its position, and the only conceivable power is that with which the air-pressure (evidently stronger in front and at the sides than behind) presses the lungs at the borders of the fluid against the chest. At first the exudate behaves in exactly the same way, and the reason it retains this original peculiarity after it has increased in size whereas the hydrothorax as it enlarges more and more follows the law of gravity, depends, in the former, upon the existence of adhesions at the edge of the exudate, which are very slowly absorbed and again pushed forward parallel to their line of formation. When the fluid of the latter (hydrothorax) attains a certain weight, and when the pressure under which it stands becomes positive, there is no longer sufficient resistance (in the absence of adhesions) to prevent free movability. Moreover, in medium-sized hydrothorax we can frequently prove that the change of level due to gravity follows but very slowly, which shows that the part of the lung in close proximity to the thorax still opposes a certain resistance to the dislocation of the fluid. The cases of pleurisy where the level of dulness runs a horizontal course are comparatively rare, and are by no means limited

to patients who walk about while the exudate is forming. In such cases some abnormal resistance behind, such as old adhesions or other pulmonary changes, probably oppose the accumulation of the exudate. All possible anomalies in the shape of the dulness may be explained by such assumption and by alterations in the elasticity of the lungs. It has been pointed out many times (Garland, Damoiseau, Ellis,¹ Heitler, and, more recently, Krönig and Hamburger) that the upper portion of pleural dulness is less intense near the spine than at some little distance from it. With a certain strength of percussion, therefore, it is possible to "bring out" an upper border of dulness, the highest point of which is at some distance from the spine. From this point the line drops both backward and forward. The author, however, does not consider this peculiarity usual nor does it conform most closely to the anatomic relations. This approximately triangular area of diminished dulness which, by this kind of percussion, can be mapped out along the spine from what the author considers the typical area of dulness, is known as "Garland's triangle." The author intentionally omitted mention of this phenomenon from his earlier edition and he believes too much stress has been laid upon it recently in the renewed and more active consideration of discoveries in physical diagnosis. In rare cases this paravertebral decrease of the dulness may be caused by an anomalous position of the exudate from adhesions; but otherwise the phenomenon under discussion belongs to the province of comparative percussion and not to topographic or border percussion, a distinction which is warmly defended in this book. As a few writers have properly emphasized, the phenomenon depends upon a stronger percussion than the author permits for determining superficial dulness. The upper part of the exudate is thinner, and so over it the dulness is less intense; hence, near the spine, vigorous percussion also evokes the resonant note of the healthy side. In fact, this is self-evident, and within any topographic percussion boundary different strengths of percussion certainly can bring out such qualitative variations in the note. They are, however, of no diagnostic value and may obscure the beginner's judgment of topographic relations. The renewed popularity of "Garland's triangle" makes this danger more imminent. As a matter of fact, "Garland's triangle" escapes demonstration if the percussion be correctly performed, i. e., is sufficiently light, and the phenomenon is in reality the result of applying incorrect principles of percussion. Hamburger² objected that recent writers, including the author, had disregarded the surface as opposed to the deep action of the percussion stroke, concerned in this phenomenon; but the author believes that those who have properly understood the theoretic discussion of the principles of topographic percussion in this book will consider his criticism unfounded. In percussing borders, to obtain sharp localization and to prevent diffusion of vibrations—in other words, to eliminate all possible surface action of the percussion blow—percussion must be as light as possible, as has been repeatedly emphasized. The author does not disregard the surface action of percussion, but he considers it an undesirable side action, which confuses all conditions and is the essential cause of all errors in percussion and which should, therefore, be avoided as much as possible.

Besides the peculiarity of the boundary line, large pleuritic exudations are characterized by the marked intensity of the dulness (*flatness*). We seldom meet so intense a dulness in pulmonary consolidation,

¹[*Ellis' Line*.—In America the line of pleuritic dulness was first described by Calvin Ellis, at the March meeting, 1873, of the Boston Society for Medical Improvement (Boston Med. and Surg. Jour., January 1, 1873). He said: "When a pleural effusion is small, it may occupy a conical portion of the pleural cavity in the sub-axillary region, where respiration and resonance may be wanting. But in a certain number of cases, when the effusion is quite large, if an accurate line be drawn, the flatness will be found to describe a curve, gradually approaching the spine toward the base of the chest, leaving a space from 1 to 3 inches broad between the spine and the line of flatness. In this space resonance will still be detected and respiration heard."

In a letter to the editors of the Boston Medical and Surgical Journal, January 23, 1874, Dr. George W. Garland reported a series of experiments on lungs of animals, in which he claims to have explained the curved line of dulness described by Ellis.

In a manual entitled *Pneumo-dynamics*, by G. W. Garland, January, 1877, p. 6, the writer says that this line was first described by Damoiseau, of Paris, and re-described by Ellis, of Boston. The latter was the first to trace its true shape.—Ed.]

²Wien. klin. Woch., 1906, No. 14.

because in the latter the bronchi usually contain air and percussion still elicits a certain amount of resonance.

Of still more importance, however, in distinguishing pleural exudates from pneumonia is the demonstration of a *dislocation of the heart and liver* (see p. 249 et seq., and 253), and of a decided enlargement of the affected side of the thorax. (See p. 33 et seq.)

Corresponding to the position of the complementary pleural sinus (Figs. 120, 121, pp. 218 and 219 et seq.), the dulness in left-sided effusions reaches lower than the left pulmonary border. The position of the latter can be determined from the position of the lung-liver boundary. A dulness will then encroach upon the upper part of Traube's semilunar space (Figs. 125 and 126), between the spleen, lung, and liver. (See Figs. 146 and 147, I.) Such a dulness can be very easily demonstrated, and when present, is diagnostic of a left-sided pleural effusion; but accord-

Fig. 146.—Dulness in left-sided pleural exudation. Diminution of Traube's space.

ing to the author's experience, left-sided exudates do not always produce this sign, because the complementary pleural sinus is often obliterated by early or previously formed firm adhesions, so that the exudate does not push into the sinus. Very large pleuritic effusions may force the diaphragm downward, so that the dulness which corresponds to the convex bowing of the diaphragm below may oftentimes project beyond the rib border as a narrow strip parallel to the costal margin (Fig. 147, I). This is rarely observed, because the intestines overlap the projection of the diaphragm.

Pleural effusions (unaccompanied by a pneumothorax, see p. 267) are rarely, if ever, freely movable with the change of the patient's position; this is conceivable only if there be no inflammatory adhesions at the borders of the exudate. Such exudates, more frequently serous than purulent, would furnish the same percussion results as a transudate (hydrothorax).

A pleural exudate limited by adhesions is more apt to be slightly movable. When the patient stands or sits up, the fluid shifts from behind forward inside the encapsulated space, presumably between the base of the lung and the diaphragm. Without any change in the boundary the intensity of the dulness thereby increases anteriorly and diminishes posteriorly. This peculiarity possesses some diagnostic importance and explains how it is possible to demonstrate plainly the existence of small exudates posteriorly only the moment a patient sits up, while later on it is much more difficult because part of the fluid flows more or less rapidly between the base of the lung and the diaphragm, resulting in a diminution both of the height and intensity of the dulness.

Light percussion is best suited to determine the boundaries of pleuritic exudates, since the dulness is superficial. Fig. 145, I, shows a frontal section of a pleuritic exudate. Above and below it is wedge-shaped, so that at the top and in Traube's space only a very light percussion could correctly determine the boundary.

If a pleuritic exudate become still larger, it compresses not only the part of the lung internal to the fluid (Fig. 145, I), but the entire lung, the pressure being exerted in the direction from the base of the lung to the apex; hence, the lung tissue above the exudate is under increased tension, and furnishes at first a hyperresonant and tympanitic note (p. 202), which soon, in consequence of diminished air content, becomes more and more dulled (p. 204). The note elicited over a pleural exudate can, therefore, at first be contrasted with the normal lung tone above it, later with a hyperresonant, tympanitic note, and finally with a relatively dulled note. In the last instance differentiation is often very difficult, but generally possible, because the note over compressed lung tissue whose bronchi still contain air sounds less intensely dulled than that over the exudate, and frequently possesses some tympanitic quality. Williams's tracheal tone (see p. 276) can sometimes be obtained when the pulmonary compression is very marked. (See Fig. 147 and the following pages for the percussion relations in large pleuritic effusions, and compare the pathologic dislocations of the cardiac and the liver dulness.)

Rauchfuss (Verh. der Gesellschaft für Kinderheilkunde, Breslau, 1904) has described a right-angled "paravertebral triangle of dulness" on the unaffected side in pleural exudate. The shorter side of the triangle is formed by the lower border of the lung from the vertebral column to a point 6 cm. or more to one side; the longer, by the vertebral column, up to the upper border of the exudate. Other authors (Baduel, Siciliano, Grocco) have also noted this phenomenon. In Italy it is known as Grocco's triangle. It may lead to a false diagnosis of effusion or of consolidation of the healthy lung. According to Rauchfuss, it is due partly to the dislocation of the mediastinum toward the unaffected side, so that the air content of the healthy lung is diminished near the vertebral column; partly to the transmission of too strong a percussion stroke along the surface (as in Garland's triangle, see p. 263) to the affected side. In the latter case it will disappear on the light percussion which the author insists upon for the determination of areas of superficial dulness. In the former cases it will persist. [The question of the clinical value of Grocco's triangle of paravertebral dulness has occasioned considerable difference of opinion in England and America; that of its mode of origin, still more. Ewart lays considerable stress upon a positive finding in the diagnosis of unilateral pleural effusion; believes that the triangle is rectilinear and not curved; acknowledges that a triangle of paravertebral dulness can also be produced by fluid accumulations in the abdomen, but states that its base is then broader than is the case in pleural effusions. In the latter neither the shape of the triangle nor its width

varies appreciably, but its highest point rises exactly to the level of the fluid itself. He considers that with a Samson pleximeter one can define the dulness more accurately than with the ordinary finger method. Ewart emphasizes the value of his so-called "Crucial Test and Counter Test" in discriminating between Grocco's triangle and one caused by some other condition. This check upon the finding consists of outlining the triangle first in the bowed, erect, or sitting posture, then in the lateral posture, the patient lying first upon the affected then upon the sound side. He claims that when the patient lies upon the affected side the triangle invariably diminishes; when upon the sound side, it persists, as in the erect posture, and is sometimes even increased in size. He has recently concluded that a Grocco triangle can be percussed out on both sides of the spine in bilateral pleural effusions as well as in ascites.

Thayer and Fabyan¹ have reviewed the subject exhaustively and have reported the existence of Grocco's sign in 30 out of 32 cases of pleural effusion. They regard the sign as practically constant in cases where there is free fluid in the pleural cavity or in which an encapsulated effusion impinges on the spine. They often found the respiratory murmur suppressed over the triangle of dulness and of a quality similar to that heard over the effusion. They confirmed Ewart's "crucial test."

Hollis² made a careful study of all the unilateral pleural effusions and pneumonias upon his service at St. Luke's Hospital and the New York Dispensary for three months. The triangle was present in about one-half of 18 cases of serous effusion, representing almost every variation in the amount of fluid. In one of them, with a very small amount of fluid, it was absent. Of 2 cases, with the chest full of fluid, it was absent in one and present in the other. As a rule, he found the highest point of the triangle lower than the level of the fluid. In 2 cases Ewart's "crucial test" failed. When, however, the patient was placed upon the sound side, the dulness was never intensified, but usually became less marked or disappeared. In 6 cases of pneumonia of one lower lobe he found the triangle twice, and once in a case of tuberculous consolidation with thickened pleura at one base. From these cases he concluded that the absence of the triangle is of no value in excluding the presence of fluid in the opposite chest, while its presence was no more than strong presumptive evidence of fluid in the opposite side. He explains the absence of the sign in so large a percentage of pleural effusions by the disposition of the fluid and of the adhesions.

All of these investigators are inclined to accept Baduel's and Siciliano's explanation—viz., that fluid in one side of the chest in contact with the spinal column will transmit a dull note to the opposite side through the medium of the spinous and transverse processes of the vertebræ and the heads of the ribs.

Although I have not considered this sign of sufficient value to keep careful notes on more than a dozen cases, my own experience coincides more nearly with Thayer's than with Hollis's. I have usually found the sign when I have looked for it, unless the fluid has been excessive or encapsulated in the lateral regions of the chest. A medium strength of percussion brings it out best, and if the finger be used as a pleximeter, the examiner must guard against touching the spine with it. "The triangle was first noted by Korányi in 1897 (in the fourth volume, p. 717, of *Belgógyászár Kezikönyze*, and again in Eulenberg's *Realencyklopädie der gesamten Heilkunde*, xiii). It was independently rediscovered and more fully described by Grocco (*Riv. crit. di clin. med.*, Firenze, 1902)."³—Ed.]

If a pleuritic exudate become absorbed except for the fibrinous coating left behind, dulness may still persist. To distinguish such a condition from a fluid exudate necessitates a very careful attention to other symptoms and to other methods of examination.

As a rule, fibrinous thickenings produce intense dulness only when they are associated with signs of thoracic contraction. In such an event the atelectasis of the lungs usually adds its share to the dulness. We have no right to argue against a fluid effusion because the signs remain stationary, as exploratory puncture has frequently convinced the author of the presence of fluid in cases where the dulness which persisted long after the beginning of the pleurisy had been attributed to fibrin-

¹ Thayer and Fabyan, *Amer. Jour. Med. Sci.*, January, 1907.

² *Med. Record*, January 13, 1906, p. 80.

³ Quoted from Osler's *Modern Medicine*, vol. iii, p. 809.

ous thickening. Tapping such a chest usually causes a severe pain, because the compressed lung cannot expand; hence, interference is contra-indicated, and one should allow it to remain as a filled cavity. The author knows a patient with such an exudate who is undertaking high mountain climbing.

The height of the dulness will not always determine the amount of the exudate. If an exudate be well encapsulated, increase or decrease of the amount of the fluid is much more apt to produce an increase or decrease in thickness than in height, changing the intensity of the dulness rather than its extent. As mentioned above (see p. 262), abnormal relations of retraction or of elasticity are responsible for abnormal positions of exudates, *e. g.*, a marked collection beneath or to the median side of the lung. In such a case neither the intensity nor the extent of the dulness affords a clue to the real condition, but only a careful study of the other appearances, such as dyspnea, dislocation of the organs, enlargement of the affected side of the thorax, etc. These are all very important in localizing the point for tapping a pleuritic effusion.

Ferber has plainly demonstrated a dulness after injecting 120 cc. of fluid into the cadaver of a twelve-year-old child, and after 400 cc. into an adult. But in the living, as shown in the results of tapping, much smaller quantities of fluid are often demonstrable by light percussion.

Dulness of Hydrothorax

In general dropsy the dulness due to the transudation of serum in the thoracic cavity corresponds to that of a pleural exudate. Here, too, with small transudates, the boundary line tends to curve downward and forward. (See p. 263.) But as soon as the fluid has reached a certain amount it becomes more or less movable, and the upper border of dulness then assumes a horizontal level in every position of the body, although at first it may change its position but slowly (p. 263). A change from the horizontal to the sitting or standing posture elevates the anterior boundary of the resonant pulmonary tone. This is an important point in making a differential diagnosis between hydrothorax and pleurisy. Hydrothorax is, for the most part, bilateral, but frequently more marked upon one than upon the other side. If patients have maintained a constrained position upon one side, the hydrothorax is ordinarily more decidedly developed on the lower side, or even limited to that side. Hydrothorax does not often produce any dislocation, because it is commonly bilateral, and because there is ordinarily an accumulation of fluid in the abdomen at the same time. Traube's space is affected the same as by a left-sided exudate except, of course, that the dulness is movable.

Increased abdominal contents, pushing up the diaphragm and the lung boundaries, often obscure the diagnosis of a coincident hydrothorax. If the patient be raised from the horizontal to the sitting posture, the anterior borders of the lungs will be pushed upward, but this is of very little help, for the sitting posture compresses the abdomen, and therefore also elevates the diaphragm. Hence, we must examine either in the standing or lateral posture. In the former, a dulness appears in front and below, although, to be sure, a slight hydrothorax may be hidden in the erect posture on account of the depression of the diaphragm (pp. 222 and 225). A comparatively large hydrothorax in the horizontal lateral posture would furnish a strip of dulness running along the vertebral column, which could easily be determined by comparing the two sides. (See Fig. 148.)

Dulness of a Pleural Exudate when Combined with a Pneumothorax

If a pneumothorax has persisted for some time, a fluid inflammatory pleural effusion commonly results, which may be either purulent or serous (sero- or pyopneumothorax). The fluid then collects beneath the air in the deepest portions of the pleural cavity, and furnishes a dull

II

Fig. 147.—Results of examination in a large left-sided pleural exudate. Pronounced dislocation of the heart, of the mediastinum, of the left lobe of the liver, and of the diaphragm. (See p. 416 et seq. for explanation of signs.)

percussion-note. Change of the patient's position produces the most decided mobility of this dulness, and such mobility is very characteris-

tic of this affection. In this condition pressure in the pleural cavity is, as a rule, strongly positive, and unless tied down by adhesions, the entire lung is separated from the thoracic wall by the air, so that the fluid can perfectly well follow the laws of gravity. The level of dulness is therefore exactly horizontal in every position of the patient. As there is no opposition, any change of posture produces an instantaneous change of the dulness (a contrast to hydrothorax). The fluid is not collected in the form of a wedge extending up between the lung and the chest-wall, as in ordinary pleurisy; but all of it is situated below the lung (Fig. 145, I). The consequence of this is that a considerable amount must be present before it becomes evident to percussion. In the beginning the exudate is sometimes completely hidden at the bottom of the thorax; and the high pressure of the pneumothorax depresses the diaphragm upon the affected side and makes it bulge downward. Not infrequently

Fig. 148.—Dulness of hydrothorax in right lateral posture.

we can demonstrate the fluid by means of the succussion murmur (see p. 301) before percussion shows anything. As it increases in size a narrow band of dulness can be made out at the base of the lung, front and back. We are apt to obtain better results from percussion if the patient bend forward; or if he lie upon the well side and we percuss above the spinal column, in the same way as in hydrothorax (Fig. 148). Figs. 149 and 193 show the results of examination in sero- and pyo-pneumothorax.

If the lung of the affected side be more or less adherent at the onset of the pneumothorax, all the signs will be atypical. Even a very small exudate may then be appreciated by percussion. Although the relations of position are atypical, we should still expect a change of position in the dulness of the fluid.

Dulness of Hemothorax

If blood collect in the pleural cavity from traumatism, from the rupture of an aneurysm, or as the result of a hemorrhagic diathesis, the resulting dulness will ordinarily correspond to that of hydrothorax. Since the blood coagulates very slowly (after the lapse of days), this dulness will usually shift with change of the patient's posture unless some inflammation ensues, when coagulation and encapsulation will very soon fix it.

Dulness Due to Consolidation of the Lung (Inflammation; Tuberculosis; Infarction)

A consolidation of the lungs presents a less intense dulness than a pleural effusion, because the bronchi ordinarily remain full of air, and so aid in producing a partially resonant tone. The dull area is generally of different shape. It is less sharply bounded, because the consolidation gradually merges into healthy lung tissue. In the neighborhood of consolidations we frequently obtain a tympanitic or hyperresonant note, so that the dulness due to a consolidation is often so-called dull tympany. (See p. 271 et seq.)

In *croupous pneumonia* the dulness is more apt to be located behind and below. (See Fig. 194.) Frequently enough it corresponds to one or more of the lobes of the lung; it may, however, overlap these borders in an irregular way. (See Figs. 120, 121, and 122.)

In *bronchopneumonic consolidations* the dulness is situated either behind and below (see Fig. 196) or at the sharp anterior and lateral lung edges, or else in a narrow strip along both sides of the spine.

In *tuberculous consolidations* the dulness is most frequently localized at the apices (see Fig. 195) and at the sharp pulmonary edges, especially at the "lingula" which bounds the superficial cardiac dulness on the left. Miliary tuberculosis generally causes no dulness, but rather a hyperresonant tone (p. 272, 3). Very thickly studded miliary tubercles may, however, produce a diffuse dulness simulating a catarrhal pneumonia or chronic tuberculosis (p. 261).

Pulmonary infarctions, if large enough to cause physical signs, commonly occasion a dulness over the lower posterior portions of the lung, which at first is diffuse and not very intense, but which gradually becomes more marked and more sharply defined. (See Fig. 196.)

Dulness from Tumors of the Lungs, of the Pleura, and of the Mediastinum, from Substernal Goiter, and from Fatty Deposits in the Mediastinum

There is little characteristic about the dulness of tumors of the lungs and pleura, and this corresponds to their atypical topography. They furnish a marked dulness only when they have reached a considerable size, and then it is apt to be more intense than the dulness of inflammatory consolidations, because in the tumor tissue there are no hollow bronchi. The intrathoracic tumors springing from the mediastinum, as well as substernal goiters, furnish a somewhat characteristic dulness over the upper end of the sternum; it projects from there laterally into the territory of the lung, where it is generally more or less distinctly separated from the cardiac dulness and has the shape of an hour-glass. If these tumors involve the pleura, they are frequently accompanied by pleuritic exudates, with the corresponding physical signs. Here may also be mentioned the dulness, described by von Hampeln, which is caused by fatty deposits in the mediastinum. This may sometimes lead to the erroneous diagnosis of a dilated heart.

Dulness of Pulmonary Cavities

Tuberculous and bronchiectatic cavities of the lung furnish a dull note if the cavity be filled with secretion instead of with air. It is quite characteristic for such a dulness to be replaced by a resonant, often a tympanitic, note after copious expectoration. But usually the dulness does not disappear completely because it is due in part to the thickening of the pulmonary tissue in the neighborhood.

Dulness from Pulmonary Edema

It is ordinarily assumed that pulmonary edema gives rise to a hyperresonant note (see the following page), yet a series of autopsies has convinced the author that if a pulmonary edema be of long duration, the air in the area infiltrated with fluid becomes absorbed or rises in bubbles into the bronchi, so that a very intense dulness may result, especially in the postero-inferior portions of the lung. This dulness can be differentiated from the dulness of consolidation by its rapid alteration and by the absence of bronchial breathing, because the bronchi, too, are mostly filled with fluid. Here it is really a sort of fluid or serous infiltration of the pulmonary parenchyma.

Dulness of Atelectasis of the Lungs

This is in general like the dulness of consolidation. *Obstruction atelectasis*, i. e., one due to a catarrh and plugging of the bronchus, with subsequent resorption of air from the alveoli, ordinarily furnishes a dulness like that of small areas of consolidation (see above). Later on the atelectasis is commonly transformed into a consolidation. *Compression atelectasis*, from dislocation or enlargement of the heart or from the crowding of the diaphragm upward and the consequent compression of the sharp pulmonary edge, also furnishes a dull tone. This occurs upon a larger scale from fluid accumulations in the pleura, where the part of the lung covered by the fluid, and later that lying above the fluid, is robbed of its air content. (See p. 265.) Marked cardiac enlargement compresses the lung and often causes a very extensive dulness of the left posterior and inferior portions of the lung. It is frequently wrongly diagnosed as a pleural effusion or pulmonary consolidation. Some pleural exudates exhibit the paravertebral triangle of dulness upon the sound side as a result of partial atelectasis. (See p. 265.)

During the formation of all kinds of atelectasis the tissue is relaxed, so that the normal tone is first transformed into a hyperresonant or tympanitic note, and finally, on account of the diminution of the air content, into a dulled note. (See p. 203.)

Dulness of Pulmonary Retraction

By pulmonary retraction is understood that chronic change of the lung which results from indurative (shrinking) consolidation and atelectasis. The result of percussion in the retraction associated with pulmonary tuberculosis corresponds essentially to that in tuberculous consolidations. The retraction resulting from a pleurisy causes either a localized dulness corresponding in shape and extent to the antecedent exudate, or if the whole lung be compressed, a diffuse relative dulness of an entire lung. Thick pleuritic adhesions or exudates which remain stationary frequently increase the intensity of the dulness.

Dulness from Diffuse Dilatation or Diverticulum of the Esophagus

(See later, Examination of the Esophagus.)

ABNORMALLY RESONANT (HYPERRESONANT) AND TYMPANITIC NOTES WITHIN THE PULMONARY BORDERS

We have already described upon p. 204 et seq. the conditions which may give rise to a hyperresonant or to a tympanitic note over an area characterized normally by a non-tympanitic one.

Hyperresonant or tympanitic notes within the pulmonary borders occur as follows:

1. In *pulmonary emphysema* diffused over the entire lung. The very typical percussion-note of emphysematous lungs is called a "box-note" ["boardlike."—Ed.]. The name is sufficiently descriptive. Some authors describe it merely as an abnormally resonant pulmonary tone; others as a low tympanitic note.

2. In *relaxation of the pulmonary tissue* from retraction due to a diminution of space in the thorax. This occurs in dislocation upward of the diaphragm, in intrathoracic and intrapulmonary tumors, in consolidation, in pleural effusions, in cardiac enlargements, and in peri-

cardial effusions. When the diaphragm is pushed upward, the note may be uniformly abnormally resonant over both lungs. If the relaxation of the pulmonary tissue be localized, as in the other cases mentioned above, the abnormally resonant note will be chiefly noticeable adjoining the cause of the decrease in space. Thus, just above the pleuritic dulness the retracted lung gives an abnormally resonant or tympanitic note. In all these conditions the more marked the relaxation of the lung, the more nearly tympanitic this abnormally resonant pulmonary tone becomes. If the space be still further decreased, so that the lung is compressed, the note becomes dull.

3. In *relaxation of the pulmonary tissues from structural changes*. To this type belong diffuse pulmonary edema and the localized inflam-

udate, in the
sitting pos-
ture

Fig. 149.—Results of percussion in a right pneumothorax—dorsal decubitus (the exudate is, therefore, not demonstrable in front): resonance overlapping the territory of the lung; dislocation of the liver, heart, and mediastinum; superficial cardiac dulness restricted at the right.

matory edema which adjoins a consolidation, both as a precursor and as a residuum of the inflammatory consolidation. With the onset of the edema the normal pulmonary tone becomes first abnormally resonant, next hyperresonant, and finally tympanitic. Pronounced edematous saturation of the lung may ultimately produce a dulness. (See p. 271.) The relaxation of the pulmonary tissue in beginning obstruction atelectasis, due to the plugging of a bronchus by secretion or by a foreign body, also belongs to this category. Another transition occurs here, as well from the hyperresonant to the tympanitic note, and finally, if the atelectasis become complete or lead to consolidation, to dulness.

4. In *pneumothorax* (Fig. 149). In most cases the percussion-note

becomes abnormally resonant, but only rarely tympanitic. The most frequent type is the so-called valve pneumothorax, in which the air is under such marked pressure that the note is usually non-tympanitic (p. 204). It is, however, generally tympanitic in open pneumothorax, where the air is under the atmospheric pressure only (postoperative empyema). The chief distinction between the normal lung tone and the note of a pneumothorax is that the latter projects noticeably beyond the normal lung boundaries, because the complementary pleural sinus is filled with air. In right pneumothorax the liver dulness is diminished from above, the cardiac dulness from the right. (See p. 241 and Fig. 149.) In left-sided pneumothorax the splenic dulness disappears and the cardiac dulness is either diminished or, more commonly, disappears (p. 241). Very frequently distinct dislocation can be observed. Sometimes, though not constantly, the resonant note over a pneumothorax presents a metallic character, which usually can only be appreciated with the stick-pleximeter method of percussion. (See p. 205.) Again, it may exhibit all sorts of variations in the pitch. (See following pages.) If the pneumothorax be combined with an inflammatory fluid effusion, and this is the rule when it has persisted for any length of time, the fluid shifts completely with change of the patient's position, and very much more rapidly than in hydrothorax. In every position of the patient we find, then, that the lower part of the thorax is dull; and that above the dulness, separated from it by an exactly horizontal line, is the resonant note of the pneumothorax (p. 269 and Fig. 149).

5. In *cavities of the lungs* (tuberculous, bronchiectatic, and abscess cavities). As a rule, the cavities are at least partly filled with secretion and they are surrounded by tuberculous or consolidated inflammatory tissue, so that percussion over them ordinarily elicits a dull note. (See p. 270.) Stronger (deep) percussion, or the expectoration of the secretion, transforms the dull into a tympanitic note. A very large cavity containing a great deal of air, or one located very superficially and surrounded only by a thin layer of consolidated pulmonary tissue, will furnish an abnormally resonant note, and even with light percussion, a tympanitic one. Smaller cavities (up to the size of several cubic centimeters), and even very large cavities, when situated deeply, generally escape demonstration by percussion. The stick-pleximeter percussion method will sometimes, though not often, demonstrate metallic resonance and change of pitch over cavities. (See pp. 205 and 275 et seq.)

6. Diaphragmatic hernias in the region of the lung, containing intestines, will cause a loud tympanitic note. They can be distinguished, especially, from pneumothorax, by their irregular shape and by the intestinal borborygmus, mostly of metallic character.

7 See p. 888, under Examination of the Esophagus, in regard to the tympanitic note of esophageal diverticula.

SPECIAL PERCUSSION PHENOMENA OVER THE THORAX

Metallic Resonance Over the Thorax

See p. 207 in regard to the origin and peculiarity of metallic resonance.

Metallic resonance is most frequently observed in *pneumothorax*. (See the preceding page.) It is favored by the size of the air space and by the smoothness of the walls, and is most readily demonstrated by the

stick-pleximeter method of percussion, combined with auscultation. Metallic resonance, is, however, not a constant sign of pneumothorax, because it requires a peculiarity in the shape of the air space and a certain degree of tension of the inclosed air. If the air exist under too slight or even under too high a pressure, the metallic resonance disappears. It often requires a certain strength of percussion to make it audible, and not infrequently it can only be appreciated at certain places. In most cases the metallic note is too weak to be appreciated at a distance, *i. e.*, without coincident auscultation.

The metallic resonance of a pneumothorax frequently disappears during aspiration; or, in case it was not present beforehand, aspiration may bring it out. This is due to the influence of the tension of the inclosed air.

The metallic resonance of a pneumothorax frequently exhibits distinct variations in pitch, depending upon whether we percuss the patient in the sitting or recumbent posture. This is plainly due to the mobility of the fluid in the pleural cavity, with change of the patient's posture. A deepening of the note in the sitting and an elevation in the recumbent posture (Biermer's change of tone) is more frequently noted than the reverse. The height of the metallic resonance varies inversely with the longest diameter of the air space (see p. 205); therefore we assume that in the former case the diaphragm, under the weight of the exudation in the sitting posture, drops downward. If the note become higher in sitting up (the reverse), we assume that it is due to the resulting diminution of the air space by the rise of the exudation in the sitting posture. The pitch of the metallic resonance varies in different places; hence, in such an examination we should always percuss the same spot.

In pneumopericardium an abnormally resonant tympanitic or non-tympanitic note takes the place of the cardiac dulness, sometimes accompanied by a dulness from the exudate and sometimes not. (See p. 242.) A blended metallic resonance similar to that of pneumothorax can at times be demonstrated. The patient's posture may also influence the intensity and the pitch of this metallic resonance (change of tension of the air, dislocation of the heart and of the exudate).

Pulmonary cavities only rarely furnish metallic resonance, because they do not often fulfil the conditions for its establishment. (See p. 205.) They are either too small, have too irregular or too thick walls, *i. e.*, are situated too deeply. The last-named factor may prevent the occurrence of metallic resonance because it opposes an interrupted vibration of the air-space. (See p. 205.) If a metallic resonance be obtained over a pulmonary cavity, similar alterations in pitch may be brought out, concerning which see pp. 208 and 275 et seq.

Diaphragmatic hernias within the thorax may also give rise to a metallic resonance (see below).

CRACKED-POT RESONANCE (CHINK OF COINS) OVER THE THORAX

Cracked-pot sound (see pp. 205 and 208 as to its origin) may be produced while percussing a normal thorax under entirely physiologic conditions, *e. g.*, over the lungs of a crying child, or, provided the thorax is yielding, over an adult's lungs while he is talking, or over some people's lungs during forced expiration with half-open vocal cords. Vigorous

percussion, proximity to the trachea, and open mouth all favor the production of this resonance. The sound under physiologic circumstances is assumed to rise at the narrowed glottis, because the percussion blow causes the sudden escape of air. (See pp. 205 and 208.)

It can also be noted over relaxed or partially consolidated pulmonary tissue under all those conditions which furnish abnormally resonant or tympanitic pulmonary tones, *e. g.*, at the borders of pleuritic exudates and in the neighborhood of consolidations. Its explanation under these circumstances is not yet entirely clear, *i. e.*, whether here, too, it is due to a stenotic murmur (pp. 205 and 208) arising, as in the crying child, at the glottis, or as seems more likely, in the latter case, *in loco*. The percussion blow may produce a momentary compression of bronchi, as well as a coincident escape of air through them. However this may be, the author's experience has convinced him that if the conditions which give rise to the noise, even in healthy persons, be absent, *i. e.*, speaking, straining while the glottis is half open, etc., cracked-pot resonance rarely results from the above-mentioned pathologic conditions (relaxation, consolidation). Cracked-pot sound has a certain significance in the diagnosis of pulmonary cavities. It is very common, especially with rather strong percussion, over small superficial cavities (a few centimeters in diameter) which, as is usual, communicate with a bronchus. It is probably due here to the production of a stenotic murmur at the opening of the bronchus into the cavity. Marked emaciation will favor the production of the sound. If the above-mentioned conditions which are apt to favor its production under normal circumstances be absent, the author attributes considerable importance to this phenomenon in the diagnosis of pulmonary cavities.

CHANGE IN THE PITCH OF THE PERCUSSION-NOTE OVER THE THORAX

Wintrich's Change of Tone and Williams' Tracheal Tone.

—If the patient open his mouth during percussion, the pitch of a tympanitic pulmonary note, or of a metallic resonance over pulmonary cavities, will be raised, while if the mouth be closed, the pitch will be deepened. This is *Wintrich's phenomenon*. The patient should breathe naturally, and the note over the two sides of the chest must, of course, be compared during the same phase of respiration, because change in the latter causes variation in the pitch. (See p. 276, *Friedreich's Phenomenon*.) It is a sign of a cavity, and arises if the cavity communicate with the bronchus and transmit the resonance into the trachea, and from there into the mouth. The pitch in the mouth must vary as it is being opened or shut, according to the laws of open and closed pipes. If we approach the ear to the patient's mouth, we can readily be convinced that the change of pitch in reality depends upon an admixture of the percussion tone with the individual tone of the mouth. Hence, *Wintrich's* change of tone is not absolutely pathognomonic of a cavity. As a matter of fact, we do observe this same sort of tone change in percussing over the supra- and infraclavicular fossæ from consolidation or contraction of the upper part of the lung or from marked compression by pleuritic exudate, because vigorous percussion will readily transmit the vibration through the thickened tissue to the main bronchus and to the trachea. The note which sounds dull to light percussion then becomes tympanitic, and opening and shutting the mouth will

evoke the same Wintrich tone change. The name *Williams' tracheal tone* has been given to this phenomenon when due to such consolidated or contracted areas of lung without cavities. If Wintrich's change of tone appear and disappear, depending upon the body posture, we speak of it as the *interrupted Wintrich tone change*, as contrasted with the *simple Wintrich tone change*. Secretion closes the communication between the cavity and the bronchus, and so the sound is not transmitted. This peculiarity will sometimes aid in differentiating the Wintrich phenomena from the Williams' tracheal tone.

Gerhardt's Tone Change (Gerhardt's Phenomenon).—If the pitch of a tympanitic note or of the metallic resonance over a pulmonary cavity change with the patient's position, we speak of this change as Gerhardt's phenomenon. Fig. 150 (a and b) explains this.

A cavity contains both air and fluid. The fluid is freely movable. The diameter of the part of the cavity containing air is longer in the recumbent than in the erect posture, or vice versa. If the lung axis of the cavity lie transversely, the note in the recumbent should be compared with that in the lateral posture. Hence, percussion will produce a note of deeper or higher pitch according to the patient's position. This would naturally lead us to believe that Gerhardt's phenomenon

Fig. 150.—Gerhardt's phenomenon.

not only demonstrates the presence of a cavity, but also the direction of its longer axis; in other words, tells us about its shape. From a practical standpoint, however, we should remember that a distinct Gerhardt's phenomenon is rare; that other methods of examination, such as auscultation, are quite as diagnostic; and besides that slight differences of percussion-notes with change of position may be, within physiologic limits, due simply to alteration in the tension of the thoracic wall without any cavity within the chest. As simple a condition as is represented in Fig. 150 is rarely observed upon the autopsy table. The cavities are more irregularly shaped, so that there is more than one long axis to influence the pitch; and, besides, the variation of the tension with change of position plays a very important part, because the walls of many cavities adhere to the costal pleura.

Wherever Gerhardt's tone change could be demonstrated exactly as is explained above, the secretion flowing forward in the sitting posture should furnish a dulness at the lower border of the tympany and so clinch the diagnosis.

Friedreich's Phenomenon, or the Respiratory Tone Change.—Inspiration raises the pitch of the tympanitic or metallic note over a cavity and expiration deepens it. This is Friedreich's phenomenon. However respiration slightly alters the pitch of the note over a per-

fectly normal lung, so that this phenomenon is not diagnostic of cavities unless it be very marked and perceived at a circumscribed and otherwise suggestive spot. The phenomenon depends upon the variable tension of the lungs in the normal case, and of the cavity-wall in the pathologic case.

Biermer's Phenomenon.—The pitch of the metallic resonance over a sero- and pyopneumothorax is deepened in the erect and raised in the recumbent posture. (See p. 205.) Biermer's change of tone is in a way identical with Gerhardt's, except that the former author limited his description to the metallic resonance over pneumothorax, and Gerhardt, to the tympanitic note over pulmonary cavities.

DEMONSTRATION BY PERCUSSION OF A DIMINISHED RESPIRATORY ACTION IN PARTIAL CONSOLIDATIONS OF THE LUNGS

For the demonstration of such partial pulmonary consolidations as cause neither obvious dulling of the percussion-note nor characteristic findings on auscultation, it is often of great interest to determine whether, over the spot in question, the same change in tone between inspiration and expiration may be noted as over neighboring or corresponding areas. Normally, especially if percussion be not too light, the note is more resonant during inspiration, on account of the increased volume of air. The determination of the absence of this physiologic difference may be sufficient to establish the diagnosis of partial consolidation. This test is especially useful in the demonstration of incipient tuberculosis at the apex. Comparison should, of course, always be made with the corresponding spot in the other lung.

COMPARATIVE PERCUSSION OF THE ABDOMEN

A. The percussion-note over the abdomen becomes *more resonant*:

1. From distention of the intestines with gas (*meteorism*). The tension of the intestinal coils is increased and so dulls the note, but the increased volume of gas seems to overbalance the dullness; therefore, the note becomes sometimes higher, sometimes deeper, according as the influence of the increase of volume or the increase of tension predominates. The increase of volume tends to deepen the pitch; the increase of tension, to raise it. The more the tension increases, the less tympanitic the note, until eventually it will resemble a hyperresonant lung tone.

2. From an accumulation of air within the peritoneal cavity, pneumoperitoneum (perforation of stomach or intestine). Here the influence of the volume of air and of the tension acts precisely as in meteorism. If the air accumulation be freely movable, it naturally occupies the highest point of the peritoneal cavity and overlaps the liver, sometimes enough to obliterate the liver dullness. If, as commonly happens, an exudate be associated with the accumulation of air in the peritoneal cavity, the inferior portions become dull. This dullness shifts exactly as in pyopneumothorax, and so always presents a horizontal level. The stick-pleximeter method of percussion ordinarily brings out or emphasizes the metallic resonance over an air accumulation in the abdominal cavity.

B. The abdominal note becomes *dulled*:

1. In a diffuse way, from diminution of the gaseous contents of the intestines (starvation, scaphoid belly of meningitis tuberculosa).

2. In a circumscribed way, from solid or fluid material filling the intestinal coils. (In regard to a possible confusion between abundant fluid in the intestine and free fluid in the peritoneal cavity, see section 6.)

3. From tumors which are situated in the intestines, which lie between the intestines and the abdominal walls, or which, arising from below, push the intestines aside. Palpation bounds these much more accurately, so that the only value of percussion is to determine whether the intestine or stomach lies in front of the tumor or not, by the presence or absence of a superficial dulness over the palpable resistance. For this purpose it goes without saying that we must employ as light a percussion as possible, in order to avoid vibrating neighboring or deeper-lying intestinal coils. It is difficult to determine deep dulness over the abdomen, so that percussion has very little value in localizing deep-lying tumors. (See p. 257.)

4. From a large number of empty and contracted intestinal coils.¹ These may produce quite an intense localized dulness.

5. From inflammatory infiltrations of the intestinal walls or of the peritoneum. Palpation also appreciates them as resistances resembling tumors. To this group belong the dulness noted in the right iliac fossa in perityphlitis and that of chronic inflammatory and tuberculous adhesions. The dulness can sometimes be sharply defined, sometimes not. Light percussion is necessary because dulness, if appreciable, is superficial. Palpation again generally furnishes more accurate data of the topographic relations.

6. From fluid effusions between the intestines and the abdominal wall. At a moderately acute stage inflammatory effusions are frequently encapsulated by adhesions, and then furnish a circumscribed, irregularly shaped dulness. Inflammatory serous effusions which are slow in their development, *e. g.*, tuberculous peritonitis, and even acute purulent effusions, are not necessarily encapsulated. We shall obtain from them a more or less intense dulness in the dependent portions of the abdomen, shifting with the patient's movement and presenting an approximately horizontal level in every position. This horizontal level of dulness may, however, frequently be interrupted at one or two places, where separate intestinal loops are adherent or where marked tympanites may press them against the abdominal wall. This change in the position of the dulness need not appear instantly in every case, even though adhesions be absent, because the distended intestines are likely to oppose some obstacle to the movement. *Ascites* or *dropsical effusions in the abdomen* (general dropsy, portal stasis) furnish similar percussion results. The dulness is always superficial, so that percussion must be light in order to bound the fluid dulness.

A free fluid effusion in the abdomen must attain considerable dimensions before it produces distinct dulness. F. Müller² found, in experimenting upon the cadaver, that in children one year old 100 cc. could not be demonstrated; that 150 cc. gave a relative dulness; and that 200 cc. gave an absolute dulness, shifting with change of position. In adults, 1000 cc. furnished no distinct dulness; but with 1500 cc. a dulness was perceptible in the dependent portions (lumbar regions); while with 2000 cc. the dulness reached a hand's breadth and became absolute. He rightly emphasized the greater accuracy of percussion of the living body; and this is in accordance with countless clinical and pathologico-anatomic experiences. The more favorable results in percussing the living depend, the writer believes, on the

¹ F. Müller, Berlin. klin. Woch., 1895, No. 13, p. 278.

² *Loc. cit.*

one hand, upon the greater elasticity of the living abdominal walls, which, therefore, furnish a better localization of the percussion blow; and, on the other hand, upon the fact that during life the movements of the intestines prevent the loss of any fluid between separate coils of intestines.

Very large fluid effusions furnish a dull note over the greater part of the abdomen. But even then a rounded tympanitic area persists very characteristically at the highest point of the abdomen, i. e., the epigastrium, corresponding to the top of the intestinal coils floating in the fluid. Free fluid effusion in the abdominal cavity can thus be differentiated from the equally marked abdominal distention due to cystic tumors. In women such cysts frequently originate in the ovaries; in men, very rarely in the pancreas. With these cysts the dulness is most marked in the middle of the abdomen, because they quickly grow toward the middle line, the direction of least resistance, and crowd the intestines backward.

(See paragraph 7 in regard to the demonstration of free fluid effusions in the abdomen, with coincident edema of the abdominal walls.)

There may occur an abdominal dulness which resembles that caused by ascites in that it changes with the position of the patient and preserves a horizontal level, but which is due to fluid in the intestine, not in the peritoneum. Such a condition is known as *pseudoascites*. The differential diagnosis between it and true ascites is generally not very difficult. Pseudo-ascites is usually characterized by the presence of diarrhea and of succussion, by the less definitely circular boundary of the dulness, and by the slower change in the position of the dulness when the patient is moved. The general clinical picture of ascites is also, of course, lacking.

7. From thickening of the abdominal walls, whether on account of fat-accumulation or of edema. The edema is ordinarily localized in the dependent portions, so that percussion may confuse it with ascites. Palpation of the abdominal walls, and the fact that the dulness does not shift with a change of the patient's position, will generally prevent a mistake. If the edema be combined with ascites, the movable fluid can sometimes be demonstrated only in the knee-chest position, because the edematous lateral walls of the abdomen furnish so much dulness.

AUSCULTATION

AUSCULTATION IN GENERAL; INSTRUMENTS

AUSCULTATION in its broadest sense means the examination of the body by the sense of hearing. It should include the appreciation of any sounds the body may furnish, whether heard near by, at a distance, or with the aid of instruments, e. g., the cough, the voice. In the narrow and more usual sense, auscultation includes only the diagnostic method of listening to the body by means of some specially constructed sound-conducting apparatus or by means of the ear directly applied.

A few experiments and essays antedated the practical listening to the interior of the body.¹ Auscultation was, however, first practically employed by Laënnec. His work upon auscultation was published in the year 1819. In it he not only instituted these methods of examination, but ventured definite conclusions which were based upon several years' study. He also invented the stethoscope. Many scholars have since then developed the scope of auscultation; among them notably Skoda,

¹ Hippocrates recognized the succussion noises, named for him, as well as the pleural rub, which he compared to the creaking of leather.

Wintrich, Zamminer, Traube, Bamberger, A. Geigel, Th. Weber, and Gerhardt.

In regard to method, we distinguish between an *immediate* or *direct* and a *mediate* or *indirect auscultation*. In the former the examiner's ear is applied directly to the patient's body; in the latter he listens with the aid of an instrument called the stethoscope.

According to the author's opinion, the essential quality of a good stethoscope is not, as was contended by Laënnec, and since his time by many others, its capability of intensifying the tone vibrations. Unless an examiner is hard of hearing, stethoscopes which transmit to the ear vibrations intensified by resonance are by no means the best, because they are bound to alter the tone to some degree. Examples of this type are the instruments of Voltolini, Hüter, and König. In that of Hüter, the opening of the sound funnel is closed by a simple rubber membrane; in that of König, by two rubber membranes with an air-space between, whose form can be changed by blowing upon it into a lens-shaped resonating chamber. The microphone, devised to intensify the sounds, has not thus far proved practical.¹ The requisite, then, for a good stethoscope is not so much the capacity to magnify as the capacity to transmit the tones to the ear, at least not markedly weakened. This essential is fulfilled by practically all the countless stethoscopes met with in practice, in the use of which we are sure that we hear only what is appreciated by the ear. The stethoscope might therefore be considered superfluous and only immediate auscultation practised. But it has certain advantages, the most important of which is that it enables us to auscultate an exactly circumscribed spot to the exclusion of the neighborhood; in other words, to exclude the sounds of adjacent body parts. In cardiac diagnosis this is absolutely necessary. On the other hand, immediate auscultation offers certain disadvantages in the direction of convenience and cleanliness; besides, in the supraclavicular it is impossible, in the infraclavicular region very difficult, to apply the ear directly. In some cases, however, especially in listening at the back, immediate auscultation is of advantage. Direct contact can then, of course, be avoided by interposing a soft towel between the patient's body and the examiner's ear. Faint bronchial breathing occurring at the beginning of pulmonary consolidation in pneumonia can often be detected only by placing the ear directly against the thorax. This is particularly true in the case of young children.

Stethoscopes have been made in the most varied forms and out of the most varied materials. They ordinarily consist of a hollow stem of wood, hard rubber, or metal, with an enlarged, slightly funnel-shaped tip at one end, and an ear plate, with a hole in the middle, fastened perpendicularly to the other end of the stem. The funnel-shaped end is placed against the skin of the patient, and the ear of the examiner is applied to the ear plate as closely as possible. The ear plate is in some

¹ The so-called *phonendoscope*, recently so extensively advertised and discussed, is in reality nothing more than the old resonance stethoscope, which long ago fell into disuse on account of the alteration of the tone. Its popularity is probably due to the name and to the appearance of the instrument. Like the microphone, its principle of construction is based upon the false assumption that the main trouble in auscultation consists in the difficulty of appreciating the sounds. Any one who has had much experience will complain rather of an embarrassment of riches in auscultation. The real difficulty lies in judging the significance of the sounds, and this difficulty will not be made any less by using an instrument which magnifies unimportant or artificial accessory noises.

[Despite the author's objections to the resonating stethoscope, its use in America is so universal that I believe a word in its support might be in place here. The choice of a stethoscope is, after all, quite a matter of custom and convenience. Many good stethoscopes are made in America, especially the Tiemann and Ford models, the favorites in New York City, and the Gannett model, so often selected by clinicians in Boston and Baltimore. The resonance is decided with any of these instruments, but I have not found that it seriously detracts from their practicability. The Bowles' model, a type of phonendoscope, is warmly recommended by many of the younger clinicians. In my opinion it has many advantages, although I still depend upon the other models for most purposes. One especial advantage is that it can often be used when another type of instrument fails, *e. g.*, when a patient is recumbent and too sick to be moved. Then, by slipping it under the patient's back, one can often obtain an approximately accurate idea of the breathing over the bases of the lungs behind.—ED.]

instruments concave, in others convex. For most observers the former shape seems to adapt itself better to the ear. To carry the instrument conveniently in the pocket, it is desirable to be able to separate the ear plate from the tube by unscrewing or in some other way. There is no advantage in substituting for the ear plate an olive-shaped peg adapted to fit into the external canal of the ear. Experiments have shown that the canal which is bored through the tube in the axis of the stethoscope should have about the same diameter as the entrance of the external ear.¹ In order not to cause the patient pain, the edge of the funnel end must be well rounded. The width of the funnel varies with different instruments. A wide funnel has the advantage of receiving sound waves over a large area, and therefore, in general, of transmitting the sounds more powerfully to the ear. On the other hand, a narrow funnel has the advantage of better isolating the sounds and of modifying them less by resonance. It is of some advantage, therefore, to possess a stethoscope with a wide funnel at one end and a narrow one at the other, in either of which the ear plate can be inserted by means of a conical peg. The funnel should not be too long. The long bell-shaped funnel ends of many hard-rubber stethoscopes really confuse the respiratory murmurs, and often in a very marked way, by resonance. The length of the cylindric part of the instrument is of minor importance.

Flexible stethoscopes transmit the sound from a funnel through a tube or tubes to the ear of the observer. This is the principle of most of the above-mentioned resonance stethoscopes. They are very convenient, especially the binaural, and a furnish a very loud tone; but the resonance is confusing, and the slightest movement in handling gives rise to perplexing murmurs. The same difficulty occurs even in the binaural stethoscope (devised recently by Camman and warmly recommended by Pel) and in similar instruments in which accompanying noises are hindered by making the sound-conducting tube partly quite firm, partly of very dense tubing. After many attempts with all these instruments, the author must recommend for practice the ordinary single-barrel stethoscope, for he is convinced that in a method of examination which is already difficult itself, it is not advisable to complicate the affair for the sake of external convenience and to use instruments which possess such essential faults. He believes that the use of flexible stethoscopes very often leads to gross diagnostic errors. They are absolutely necessary only for auscultating one's own body.

The Technic of Auscultation.—The stethoscope should be applied very carefully, so that the edge of the funnel makes an air-tight connection with the skin; the ear should be lightly applied to the ear plate without leaning the head upon it. Tilting the stethoscope should be avoided, because it is very painful for the patient and prevents correct auscultation. The best way is to hold the stem with the thumb and forefinger lightly applied near the funnel end, so that the slightest movement can be readily felt and corrected. In direct auscultation the ear should be placed in close contact with the body. It is often well to close the other ear with the finger.

AUSCULTATION OF THE RESPIRATORY ORGANS

The immediate, as well as the mediate, method should be used in auscultating the lungs, for some sounds, such as faint bronchial breathing (see p. 288), are better appreciated by applying the ear directly to the chest, and an exact localization is of less value than in cardiac diagnosis.

It is exactly in these cases (in general rare), where the tones are so weak as to be indistinguishable, that the tone-increasing or resonating stethoscope is useless, for its modification of the sounds increases the difficulty. It may so destroy the sharp distinction between vesicular and bronchial breathing that gross errors result. The sources of error which may arise from involuntarily moving the stethoscope while auscultating the lungs will be mentioned later.

It is advisable to auscultate during normal, and then during exaggerated, respiration, and over any suggestive places both during and after cough, as well as to listen in such places to the loud and the whispered voice.

¹ A form of stethoscope, long abandoned as impracticable, but recently revived, has a solid instead of a hollow stem. This, however, does not convey the sound properly and should be discarded.

THE NORMAL VESICULAR RESPIRATORY MURMUR

A characteristic sighing or sipping noise, perhaps resembling a very soft "f," is heard over a healthy lung throughout inspiration; during expiration there is either no sound, or at the beginning a very short, faint noise. The latter is rather difficult to describe; it is apt to be lower pitched than the murmur during inspiration, and is slightly rustling, or over certain places slightly blowing, in character. Its duration corresponds normally to less than a fifth of that of the inspiratory murmur. These two sounds constitute the normal breathing murmur—the so-called vesicular breathing. Its presence shows us that the lung parenchyma at the spot of auscultation not only contains air, but also breathes—that is, during inspiration air enters the alveoli. The inspiratory murmur is evidently the essential characteristic of vesicular breathing.

Numerous theories have been suggested in explanation of this vesicular breathing, but as yet there is no one definitely accepted. Laënnec, the inventor of auscultation, assumed that vesicular breathing was caused by the rubbing of the inspiratory air stream against the walls of the fine bronchi or infundibula. But if friction exist, it must act, not between the walls and the air, but between the outer layer of air, which rests nearly motionless against the walls, and the more central actively moving current. Laënnec's theory, however, did not lay any emphasis upon the friction taking place at the outer boundary of the air stream, *i. e.*, between the air and the walls of the bronchi and infundibuli, and might be stated to-day by saying vesicular breathing is the acoustic expression of the friction caused by the entry of air into the pulmonary parenchyma. It has also been objected that the current of air entering the bronchi during inspiration is not rapid enough to cause friction noises.

Baas has advanced a more recent theory, which many authors believe disproves Laënnec's. Vesicular breathing he regards as a modification of the blowing noise which arises in the larynx and trachea during respiration, which is transmitted through the bronchi to the interior of the lungs, and thence through the air-containing lung to the observer's ear, and which acquires, because of the interposed air-containing tissue of the lung, its sipping vesicular quality. The following experiment was made in proof: An inflated lung was placed upon the larynx of a living man, the laryngotracheal murmur was auscultated through this lung, and it was expected that the blowing murmur would be transformed into a sipping vesicular breathing by the air-containing lung. The author has never heard anything but a weakened blowing tracheal murmur in performing this experiment. It is, in fact, difficult to imagine how the tracheal murmur, with an expiratory portion the equal of or stronger than the inspiratory portion, could be both qualitatively and quantitatively modified by the interposition of an air-containing lung. Nor does clinical evidence support Baas' theory, for, as soon as a bronchus is plugged by secretion or by a foreign body, no vesicular breathing can be heard over the pulmonary area supplied by that bronchus until the bronchus becomes free again. This surely proves that inspiratory filling of the lung with air is necessary to produce vesicular breathing. The pathologic modifications of vesicular breathing similarly disprove the Baas theory, *e. g.*, we hear an intensified vesicular

breathing over circumscribed areas of lung when, for some reason, the breathing is more vigorous (compensatory); and, on the contrary, a localized diminished breathing wherever, for any reason, the corresponding lung area is limited in its movement (through lack of room or adhesions). Again, despite the increase of the laryngeal breathing noise in laryngeal stenosis, diminished vesicular breathing is heard over the lung. Further, the thicker the layer of lung, the more intense is the vesicular breathing, although, according to this theory, it should be diminished. Finally, systolic vesicular breathing, a respiratory murmur synchronous with the cardiac systole and not in the least dependent upon a laryngotracheal breathing murmur, speaks with certainty against the Baas theory, and decidedly favors the idea that vesicular breathing depends upon the pulmonary excursion. The author considers these arguments sufficient to discountenance Baas' theory.

Now, after all this critical discussion, what is the real explanation of vesicular breathing? In the author's study of the origin of vesicular breathing he demonstrated upon a man with congenital fissure of the sternum¹ that vesicular breathing arises from inflation of the lung tissue, even with the exclusion of every laryngotracheal murmur. This man had a hernia of the lung in the region of the sternal fissure which protruded externally to a marked degree when the patient strained, *i. e.*, increased his intra-abdominal tension. When this pulmonary hernia was auscultated at the same time that the patient strained, the most distinct vesicular breathing was heard, which was due to an expiratory filling of the pulmonary alveoli, and, since the laryngotracheal murmur was excluded by the closure of the glottis, we obtained a certain proof that the murmur of vesicular breathing is due to the local inspiratory movements of the pulmonary parenchyma. The author has recently had an opportunity to make a similar examination of the pulmonary apices of an emphysematous subject, which became inflated like balloons when the patient strained (Valsalva's experiment), and over which could be heard distinct vesicular breathing. In these examinations he could not determine whether the vesicular murmur was produced by the distention of the pulmonary tissue or by the friction in the interior of the inspiratory air stream in the smallest bronchi and alveoli. That is a fine point of no great significance. Stretching of the lung tissue may cause the murmur. The distention of separate lung alveoli doubtless does not happen at the same instant, and may produce a series of vibrations lasting over the entire inspiratory period, which together may cause the vesicular murmur.

To explain the normal brief expiratory murmur we must assume either that the weak remnant of the laryngotracheal breathing murmur is transmitted from the bronchi, or else that the expiratory murmur arises, like the vesicular inspiration, locally, through movements and rubbing in the lung during expiration. If the expiratory murmur have a plain blowing character, like that of the laryngotracheal murmur, the former hypothesis may be entertained. It should then be classed under the so-called physiologic bronchial breathing. (See p. 284 et seq.) If this blowing character be lacking, the expiratory murmur probably comes from within the lung, especially because the expiratory, like the inspiratory, murmur may be modified by local lung changes. The prolonged expiration in catarrh (see p. 287 et seq.) can be explained only

¹ Correspondenzb. f. Schweizer Aerzte, 1892.

by assuming such a localized origin. The elastic retraction of the lung in the beginning of expiration must be strongest and quickest; hence, the expiratory murmur is normally to be heard only at the very beginning of expiration.

Systolic vesicular breathing (mentioned above) is occasionally to be found both in healthy and in diseased individuals. Its origin is unknown; it has no pathologic significance, is heard only in the neighborhood of the heart, in slightly marked instances merely as a systolic accentuation of regular vesicular breathing. It certainly depends upon variations of the intrathoracic negative pressure (especially in the cardiac region) connected with the systolic diminution in the size of the heart (meiocardia). Many so-called accidental heart murmurs (see later) are nothing more than systolic vesicular breathing. Interrupted or cog-wheel breathing (see p. 287), if heard only in the neighborhood of the heart and if the interruptions be synchronous with the pulse, may, under some circumstances, depend upon the systolic accentuation of vesicular breathing.

PHYSIOLOGIC BRONCHIAL (MIXED) BREATHING MURMUR

Over certain areas of the normal lungs the respiratory murmur sounds bronchial. Such a murmur corresponds in most essentials to the laryngotracheal breathing heard over the larynx (p. 282). In contrast to the vesicular, bronchial breathing presents a blowing character and approaches to a definite pitch. We can reproduce the sound quite perfectly by vigorously inspiring and expiring with the mouth fixed as if about to pronounce the syllable "ha." We can simulate different pitches by changing the position of the mouth. In physiologic bronchial breathing expiration lasts longer and is more strongly accentuated than inspiration, exactly the reverse of the relation between them in vesicular breathing. The rima glottidis is narrowed during expiration, and that is a sufficient cause for an expiratory stenotic murmur or for an accentuation, as well as for its prolonged duration. Physiologic bronchial breathing is nothing more than the laryngotracheal murmur which originates at the upper air-passages and is transmitted through the bronchi to certain areas over the lungs. Its intensity varies considerably in accordance with the individual peculiarities of acoustic transmission. In many men the laryngotracheal murmur is audible only over the neck, while all over the lung pure vesicular breathing can be heard; in others it is audible as physiologic bronchial breathing over more or less of the lung. Physiologic bronchial breathing is most frequently audible anteriorly over the superior portions of the lungs, and posteriorly in the interscapular space. This is due to the location of the trachea and great bronchi. The right bronchus is wider and a more direct continuation of the trachea than the left; hence this breathing is naturally more evident upon the right side and sometimes also over the upper part of the sternum. Vesicular breathing is almost always to be heard at the same time with the physiologic bronchial breathing; but if the respiration be especially faint, then the physiologic bronchial breathing will alone be heard, *e. g.*, a thick thoracic wall renders the appreciation of the vesicular breathing difficult. A so-called *mixed breathing* is, however, the general rule, *i. e.*, during inspiration the vesicular, and during expiration the bronchial, character predominates. *Forced breathing, dyspnea, thinness of the thorax, any changes in the larynx and trachea which favor the production of a strong stenotic murmur (compression of the trachea from the side by a goiter¹ and the like)*

¹ In such a case the expression "physiologic bronchial breathing" signifies merely that the phenomenon does not depend upon any pathologic changes in the lung.

—all these will intensify physiologic bronchial breathing. A suggestion of physiologic bronchial breathing may very rarely be heard all over the lung, but more frequently along the spine and over most of the sternum.

Physiologic bronchial breathing may depend in some persons upon certain peculiar positions of the mouth. It may be considerably influenced, intensified, diminished, or even caused to disappear by altering the position of the mouth.

ALTERATIONS OF VESICULAR BREATHING UNDER PHYSIOLOGIC AND PATHOLOGIC CONDITIONS

INCREASED (PUERILE) AND WEAKENED VESICULAR BREATHING

The intensity of the vesicular breathing varies with the depth of the respiration and with the spot auscultated. It is weaker at the apices and borders, where the layer of pulmonary tissue is thin, than over the thick parts of the lung. Thick thoracic walls also weaken it. Children present an exceptionally loud and strong vesicular, so-called *puerile* breathing, with which physiologic bronchial breathing is often especially plainly mixed. Beginners are apt to mistake it for a pathologic phenomenon.

Pathologically, increased vesicular breathing is best designated as *sharp* or *increased vesicular breathing*. The author emphasizes these two adjectives because the expressions *sharp* or *increased* vesicular breathing and *rough* vesicular breathing (in regard to the latter, see p. 287), though fundamentally different from the acoustic standpoint, are often used synonymously. If ordinary vesicular breathing be represented by the sound of a soft *f*, increased vesicular breathing roughly corresponds to the consonants *ff*. The physiologic increased breathing (see preceding paragraph) must first be taken into account before we decide that increased vesicular breathing is pathologic.

Pathologically, increased vesicular breathing depends most frequently upon a *catarrh of the finer bronchial tubes*. The latter are narrowed by the swollen mucous membrane, and this stenosis presumably causes the increased breathing. This explanation would naturally support the friction theory of vesicular breathing, and would negative Baas' theory.

Another cause for pathologically increased vesicular breathing is the more active breathing of a certain portion of the lung. This happens wherever part of a lung is retracted or relaxed, and is generally accompanied by an abnormally loud or tympanitic percussion-note. (See p. 271.) Thus, we frequently hear increased vesicular breathing in *the first stage of croupous pneumonia*, in *the neighborhood of consolidations*, or in *the neighborhood of affections of the thoracic cavity which limit the space*, etc. In pleurisy with effusion and in pneumothorax the respiratory murmur is diminished or absent over one-half of the thorax, despite the pronounced retraction of the lung. But over the other chest-half the breathing is *increased* vicariously. The same condition is often noted in pneumonia and in pulmonary tumors.

Increased vesicular breathing is of special importance in demonstrating multiple small areas of consolidation which furnish no other auscultatory or percussion signs. The increase depends partly upon the retraction and relaxation of the neighboring pulmonary tissue, partly upon the accompanying localized catarrh. For this reason increased

vesicular breathing localized over one apex is an important sign for recognizing incipient tuberculosis, and especially so because at the apex, where tuberculosis most frequently makes its first appearance, vesicular breathing is normally weak.

Weakness, diminution, or absence of vesicular breathing is observed under manifold conditions. Careful attention should be given to the physiologic variations before we can assume any pathologic changes. Any cause which limits the inspiratory distention of the pulmonary parenchyma will diminish and finally abolish the vesicular breathing, *e. g.*, any obstacle to respiration situated in the larger air-passages. If the obstacle be located in the larynx or trachea, the respiratory murmur will be diminished over both lungs. If located in one bronchus, it will be diminished over the entire pulmonary territory supplied by that bronchus. This furnishes us with a means of estimating the degree of laryngeal stenosis in croup and of determining any extension of the croupous process down into one or the other bronchus. A localized diminution or abolition of the vesicular breathing is important for estimating the position of a foreign body in the bronchus.¹ The respiratory murmur is diminished in certain forms of catarrh which cause an exceptionally marked stenosis of the affected bronchi. The murmur is abolished in obturation atelectasis.

Even if the air-passages be free, diminished breathing will be observed when any sort of mechanical obstruction prevents the normal alveolar distention, *e. g.*, firm pleural adhesions which limit the lung excursions. Multiple small consolidations often diminish or abolish the vesicular breathing because, to a certain extent, they make the intervening portions of the lung, which are still pervious to air, stiff and inexpandible. Increased vesicular breathing is, however, also commonly heard over multiple small consolidations (see above).

Such a localized diminution of the respiratory murmur, whether depending upon a circumscribed catarrh stenosing the bronchi, or upon fixation of the lung by small areas of consolidation, or by pleural adhesions, is very important in diagnosing circumscribed tuberculous areas. Sometimes, though rarely, even a considerable tuberculous consolidation does not show the expected pathologic bronchial breathing, but diminished vesicular breathing. This peculiarity of many tuberculous consolidations, as contrasted with other kinds of pulmonary consolidation, can be explained by the frequent narrowing or contraction of the bronchial lumen in tuberculosis.

Diminished breathing is observed in pleurisy over the affected side, even at the places where the lung lies against the thoracic wall, because either the exudate or the pain limits the excursions of that side.

An emphysematous lung makes very slight excursions, on account of its permanent inspiratory position; hence the respiratory murmur is frequently diminished. But a coincident catarrh of the bronchi will tend to intensify the respiratory murmur, and so the final result will naturally depend upon the factor which is in excess. Diminished breathing is one of the cardinal symptoms of *pleurisy*, *hydrothorax*, *pneumothorax*, and *pulmonary tumors*, for two reasons: In the first place, the excursion of the affected side is limited; and in the second place, the transmission of the breathing to the examiner's ear is impaired by the interposition of fluid or solid tissue or of air.

¹ [The x-ray will usually settle this point.—Ed.]

VESICULAR BREATHING WITH PROLONGED EXPIRATION

Normally, we hear only a very short, faint murmur or none at all over the lung during expiration. But under some circumstances the expiratory murmur may be increased and prolonged until it lasts even longer than inspiration.

Prolonged expiration is a frequent, though not constant, accompaniment of increased vesicular breathing. It occurs in bronchitis, probably because the swollen mucous membrane opposes an obstacle to the respiratory current, and produces a stenotic murmur with expiration. Expiration, as is well known, is less powerful and slower than inspiration, and the stenosis slows it still more. If the catarrh be localized at certain places, the prolonged expiration also will be a local phenomenon. The prolonged expiratory murmur in the catarrh of emphysema and in asthmatic paroxysms is very pronounced and is diffused over the entire lung. In such cases the expiratory movement of the thorax is in itself prolonged. (See p. 95 et seq.) Increased and prolonged expiration is a symptom of catarrh; and, therefore, if it be localized, it has the same significance in the diagnosis of diseased areas (consolidation, tuberculosis) as has localized increased or diminished vesicular breathing (pp. 285 and 286).

F. Müller has, however, called attention to the fact that the normal expiratory murmur over the right apex is frequently increased or prolonged in comparison with that over the left. This coincides with the greater distinctness of the physiologic bronchial breathing on the right side. (See p. 284.) If this fact be not kept in mind, a false diagnosis of tuberculosis may be made. On the right side, therefore, only very considerable variations from the normal should be given weight, especially if other signs (dulness, râles, retraction) be absent.

ROUGH OR IMPURE AND COG-WHEEL VESICULAR BREATHING

Rough vesicular breathing is an impure, slightly uneven murmur, heard during inspiration, as if strange accompanying noises were admixed with the normal vesicular murmur. In order to prevent confusion with sharp or increased vesicular breathing (p. 285), the term impure breathing should be used. Increased breathing is exquisitely pure and generally very intense, whereas rough breathing is more frequently faint and indistinct.

Impure as well as increased breathing is a sign of bronchial catarrh, and may or may not be accompanied by prolonged expiration. Either the partial impermeability of the bronchi produces unequal respiratory excursions of the lung area in question, or else accompanying noises derived from the presence of secretion are mixed with the pure vesicular murmur. If these accompanying noises can be plainly isolated, we call them *râles* (see p. 293), but if they remain indistinct and blended, the vesicular breathing becomes impure or rough.

The so-called *cog-wheel respiration* resembles impure breathing, but is characterized by jerky, intermittent pauses in the inspiratory murmur or by accompanying noises which plainly separate the individual portions of the murmur from each other. In contrast to impure breathing, these individual portions retain their smooth sighing or sipping character. The acoustic peculiarities of cog-wheel respiration convince us that it is caused by the air-current being forced into the alveoli with effort and intermittently overcoming some obstacles. Cog-wheel respiration localized over a definite area of the lung is also a sign of catarrh,

and it is natural to assume that such intermittent obstruction to the respiration is due either to valve-like swellings of the mucous membrane or to accumulations of secretion which must be pushed aside by the air-current. Hence its relationship to impure or rough breathing. Naturally, cog-wheel inspiration may also be an increased or diminished breathing and may be associated with prolonged expiration. Sometimes the expiration is also cog-wheel in type.

Hensen¹ has called attention to the fact that in many cases of cog-wheel breathing the intermissions are synchronous with the pulse (*pulsating cog-wheel breathing*). He explains this phenomenon by the supposition that hyperemia of the lung is responsible for this form of cog-wheel breathing, the pulsation of the pulmonary arteries rhythmically decreasing and increasing the respiratory movements. This pulsating character, however, may be explained equally well by the previous statements if we bear in mind that every systole of the heart lowers the intrathoracic pressure and, consequently, through the mechanism of the systolic vesicular breathing (see p. 284), accelerates the inspiratory air-current. The latter explanation ought, then, to apply to those cases in which the pulsating cog-wheel breathing is audible only in the neighborhood of the heart. It is also conceivable that even in the absence of pulmonary hyperemia the pulsation of the pulmonary arteries may give to ordinary cog-wheel breathing, caused by an obstacle in the smaller bronchi, a rhythm synchronous with the pulse. C. Gerhardt maintains that insufficiency of the pulmonary valves may cause pulsating cog-wheel breathing by the systolic expansion of the arteries of the lung arising from the *pulsus celer*.

There is another kind of cog-wheel respiration not at all dependent upon the pulmonary, bronchial, or cardiac condition, but upon uneven or intermittent action of the inspiratory muscles. This occurs by no means rarely in partial paralyses and during fatigue of the respiratory muscles. It can be distinguished from the form described above by its more even distribution over the entire lung and by the fact that it is not synchronous with the pulse.

PATHOLOGIC BRONCHIAL BREATHING

Pathologic bronchial breathing is a blowing murmur heard over morbid areas, and is practically identical with the sound we have already described under the term physiologic bronchial breathing, *i. e.*, with a laryngotracheal murmur resembling the syllable "ha." From experience we have learned that it is to be heard wherever the pulmonary parenchyma is airless (whether on account of external compression or on account of consolidation), wherever there are pathologic pulmonary cavities which freely communicate with the bronchus, and wherever a diffuse or sacculated dilatation of the bronchi exists.

One of the oldest explanations of the origin of bronchial breathing over solid portions of the lung assumed that the vesicular breathing disappeared and that the laryngotracheal murmur was transmitted more plainly to the surface of the thorax through the thickened lung parenchyma than through the air-containing tissue. But this explanation is not tenable, because we can prove that a solid organ does not transmit this murmur so well as does the air-containing lung. However, although the hepatized tissue itself does not transmit the laryngeal murmur better than the normal lung, nevertheless the air-containing bronchi incased in a solid tissue are better conductors than when incased in air-containing tissue.

This modified explanation is to-day rather generally accepted, but it, too, is insufficient, for in pneumonia bronchial breathing is heard not only over the consolidated area, but also in its vicinity and upon the opposite (healthy) side in the neighborhood of the spinal column. With such a result we sometimes erroneously diagnose a double pneumonia, and learn at the autopsy that the bronchial breathing must have been

¹ Arch. f. klin. Med., 1902, vol. lxxiv, p. 237.

transmitted from the affected side. This transmission of bronchial breathing shows how imperfect the preceding theory is, for it demonstrates that bronchial breathing can be very well transmitted to a distance in air-containing tissue. If, then, the bronchial breathing be really as intense in the normal bronchi as in the infiltrated tissue, how can we explain why in sound lungs it should not be able to reach the examiner's ear? The vesicular breathing certainly does not conceal the bronchial breathing, because both in transmitted bronchial breathing and also under other circumstances (mixed breathing, see p. 284) we can appreciate at the same time both a bronchial and a vesicular murmur. The author explains the transmission of bronchial breathing through healthy portions of the lung in the neighborhood of a consolidation by assuming that the consolidated lung not only transmits the laryngeal murmur to the surface through the bronchi, but magnifies it. It is evident that such an increase in a portion of the lung immovable on account of the consolidation would be produced best by resonation or consonation (Skoda). The variations observed in the pitch of bronchial breathing (p. 270) show that real resonating phenomena can appear in the bronchi of consolidated portions of lung. This question of resonance will be discussed under Consonating Râles.

Fig. 151 explains another cause of the increase of bronchial breathing over consolidated areas. Here *a b c d* represent a consolidated, *a f e d* a non-consolidated, bronchial area, with the tributary bronchi *g h* and *g i*. As a consequence of the consolidation the air-current between *h* and *g* ceases, whereas that from *g* to *i* persists, so that at the point *g* the current conditions are decidedly altered. The current of

Lung tissue containing air	Solidified lung tissue (not containing air)
-------------------------------	--

Fig. 151.

air *i g* blows over a quiet column of air and might very likely produce bronchial breathing similarly to the noise made by blowing over the opening of a key.

Pathologic bronchial breathing is sometimes, although rarely, heard louder during inspiration, and not, as is the laryngeal murmur, during expiration. This fact, it seems to the author, argues in favor of the last-mentioned theory of the origin or increase of bronchial breathing, and cannot be explained by mere conduction and resonation.

The result of this discussion should lead us to conclude that better transmission of the laryngotracheal murmur is not sufficient to explain the presence of pathologic bronchial breathing over pulmonary consolidation, but rather that the laryngotracheal murmur comes much better to the surface in solid tissue with open bronchi, and that in the thickest portions it is even intensified.

There is no appreciable acoustic difference in the bronchial breathing whether the pulmonary consolidation consists in an infiltration of the alveoli with inflammation products, or in an atelectasis from compression of a pleuritic exudate, pneumothorax, hydrothorax, or pericardial exudate. Naturally, this compression of the lungs must be limited to the alveoli alone and not involve bronchi, at least not those of any size. For as soon as an effusion, for example, increases enough to compress the larger bronchi, the bronchial breathing, which is frequently heard with

difficulty on account of the interposition of the e and fainter and finally disappears.

Obturation atelectasis, due to the plugging consequent resorption of air from the alveoli, prevents bronchial breathing, and in spite of the pulmonic of the consequent dulness, no respiratory murmur can be transmitted from the neighborhood.

Even very tiny areas of consolidation, too small to note, may cause bronchial breathing. This shows its value in diagnosis, and is another argument against the theory of bronchial breathing.

Bronchial breathing is also heard over pleural cavities which communicate with the bronchi, and over the bronchi themselves. Here it is probably due to the laryngeal murmur, especially if the cavities lie superficially. Besides, such cavities are also lined by consolidated tissue, so that resonance contributes to the increase of the laryngeal murmur. Finally, it is noted that under some circumstances a cavity itself becomes a current of air streams through the entrance and back of the bronchus and back again. And this would cause a murmur, just as in the larynx.

Sometimes it requires very deep respirations for bronchial breathing to be audible. Again, closure of the bronchi will interrupt the bronchial breathing. Hence, when the bronchi are open, the bronchial breathing will reappear. A good way of eliciting faint bronchial breathing, if a patient cannot breathe deeply, consists in having the patient count aloud during one respiration, while the examiner breathes. Inspiration will be a maximum. This method has been used in demonstrating bronchophony. (See p. 302.) The chest will sometimes appreciate faint bronchial breathing with the interposition of the stethoscope (p. 281) in young children. It is advantageous to close the stethoscope with the finger.

DIFFERENT KINDS OF PATHOLOGIC BRONCHIAL BREATHING

Bronchial, far more than vesicular, breathing is affected by conditions (p. 288), which may vary quite decidedly. The quality can be reproduced by fixing the mouth in the positions of the vowels "ha," "he," "hi," "ho," "hu," and "hoo," and by varying the pitch.

The pitch of bronchial breathing depends in part upon the conditions of resonation, and with them upon the position of the cavities. But up to the present time it has not been distinguished so-called amphoric breathing, though it occupies an important place in diagnosis. By *amphoric* we mean a very deep and soft and generally rattle-like breathing, heard especially over large cavities (pneumothorax). Besides its low pitch and its characteristic metallic quality, apparently due to the resonance in the cavity. Amphoric breathing is sometimes associated with a metallic percussion-note.

by whispering the syllable "hu" or by blowing over an empty jar; whence the name. Provided that we do not call every deep bronchial breathing *amphoric* (a frequent mistake), amphoric breathing is a pretty sure sign of a cavity. The metallic resonance accompanying it is confirmatory evidence. Like metallic percussion, amphoric breathing excluding that found in pneumothorax arises, for the most part, only over cavities which are at least 6 cm. in diameter (according to the ordinary estimate); but it is sometimes found over smaller cavities.

Amphoric respiration may be heard over a pneumothorax from resonation if, as is most common, it be a closed, or valve, pneumothorax.

The pitch of amphoric breathing, i. e., of its metallic resonance, may vary in accordance with laws similar to those governing the metallic percussion resonance. (See the paragraphs upon the Change in Percussion-note, p. 275 et seq.)

Metallic breathing is to be distinguished from amphoric breathing. It is a murmur with high metallic overtones and without the deep basal tones. If a basal tone be audible at all, it is high, not deep. Metallic breathing may be heard over consolidation, provided the conditions are favorable for resonance, and particularly over small pathologic cavities or dilatations of the bronchi.

The respiratory murmur may in rare cases assume an amphoric or metallic character on account of the resonation set up in neighboring physiologic air-containing cavities, such as the stomach or the distended intestines.

In marked dyspnea certain positions of the open mouth may add an amphoric resonance to pathologic or physiologic bronchial breathing. But such amphoric breathing can be appreciated at a distance, and, besides, is distributed exactly like physiologic bronchial breathing, so no confusion need result. Moreover, it disappears when the mouth is closed.

METAMORPHOSED BREATHING MURMUR

Metamorphosed breathing is essentially bronchial in type. In the more common form inspiration begins sharp, blowing, and bronchial, gradually becoming much softer, and sometimes ending in amphoric breathing. In another variety the pitch of the bronchial element changes during inspiration or during expiration or during both. Either type, if heard continuously, is a practically sure sign of a cavity, provided it persists. Probably after the inspiration has lasted for a certain time it distends the cavity and its orifice enough to modify the pitch of the respiratory murmur. The author once succeeded in demonstrating two different metamorphosed breathing murmurs over adjacent areas (one higher during inspiration, the other deeper), and in making a diagnosis, which was later confirmed by autopsy, of two small abscess cavities situated near together. A similar but transitory metamorphosed breathing murmur might arise even without the existence of a cavity if the inspiratory current pushed aside the secretion of a partially occluded bronchus. Laënnec's "souffle voilé" is another variety. It begins as vesicular and then changes into bronchial or mixed breathing. (See p. 292.) The vesicular element in this case is probably transmitted. (See p. 292.) It occurs principally over tuberculous consolidations.

INDEFINITE BREATHING MURMUR

This is neither vesicular nor bronchial, but sounds like the expiratory portion of normal breathing. The term indefinite is applied also to breathing which is very faint and difficult to hear. Both bronchial and vesicular breathing may be diminished enough by a pleural exudation to become transformed into indefinite. Sometimes the breathing becomes indefinite because it is masked by other louder noises (râles or friction sounds). The true nature of indefinite breathing can often be brought out after the patient breathes deeply. Loud, distinct breathing is never indefinite, nor is the mixed murmur (to be described below). The only diagnostic significance of indefinite breathing is that of a very weakened murmur whose vesicular, bronchial, or mixed origin cannot be determined.

MIXED BREATHING MURMURS [BRONCHOVESICULAR BREATHING.—ED.]

There are two main types of mixed [bronchovesicular.—Ed.] breathing:

1. Vesicular inspiration with bronchial expiration.
2. Mixed inspiration, *i. e.*, inspiration which is both vesicular and bronchial, with bronchial expiration.

The conditions of origin of bronchial and of vesicular breathing differ so manifestly that, at first sight, it would seem difficult to explain these mixed murmurs. Practically, however, the vesicular and bronchial elements never arise from one spot, but each is transmitted from some distance and heard in combination with the other; and so a mixed murmur entitles us to assume that there exist in close proximity both normal pulmonary tissue and tissue so altered as to produce bronchial breathing. Thus, mixed [bronchovesicular.—Ed.] breathing is to be heard: (a) over portions of the lung containing scattered small consolidations; (b) over normal pulmonary tissue near large consolidations; (c) in the neighborhood of the upper boundaries of dulness of a pleural effusion which compresses the inferior while permitting free breathing of the superior portion of the lung; (d) over cavities surrounded by healthy lung tissue, etc. The importance of mixed [bronchovesicular.—Ed.] breathing in disclosing small areas of consolidation is evident, because such areas need not produce any dulness.

Physiologic bronchial breathing is almost always combined with vesicular breathing. This is important in differentiating physiologic from pathologic bronchial breathing. But the latter may also be mixed with vesicular breathing, and the distinction between physiologic and pathologic mixed breathing is as difficult as it is important. Physiologic mixed breathing is especially common over certain areas, mentioned above (see p. 284), whereas pathologic mixed breathing may be heard over any part of the lung. Even where physiologic mixed breathing is diffused over a large area, we can easily determine that the nearer we listen to the greater bronchi or the roots of the lungs, the stronger the bronchial element becomes; and, conversely, the farther from them, the weaker. If the bronchial element increase with the distance from the lung roots, we may infer that it is pathologic mixed breathing. Physiologic mixed breathing is much more affected by the intensity of the laryngeal murmur and by the position of the mouth than is

pathologic. The character of bronchovesicular breathing often varies at different examinations, being at the one time plainly vesicular, at another, bronchial. This is supposed to be due to secretion plugging a bronchus, at one time in the consolidated area, at another in the normal area. In the former case the bronchial, in the latter the vesicular, component is weakened or disappears.

There is still another type of mixed breathing which is of diagnostic importance. Mixed breathing is sometimes heard over a considerable area of the lung, loudest near the hilum (physiologic type); or, conversely, near the pulmonary edges. If accompanied by a chronic cough, but with no other evidence of pulmonary infiltration or tuberculosis, it would argue very strongly for diffuse bronchiectasis.

The device for recognizing weak bronchial breathing (p. 291 et seq.) also aids in differentiating mixed from pure vesicular breathing.

RÂLES (Rhonchi)

Under this term are included all sounds which are caused by the motion in the bronchi, not only of air, but of secretions or of other fluid, semifluid or solid materials. Such motion may be caused either by breathing or by coughing. Moist râles depend upon fluid; dry râles upon solid, material within the bronchi. To determine râles exactly and to analyze them carefully we must auscultate the patient during deep as well as during quiet breathing, and also during and following a cough. No other auscultatory phenomenon are so markedly altered by such a variation in the type of examination. Coughing, for instance, will oftentimes cause râles either to appear or disappear. If a patient be difficult to examine, if he cannot be persuaded to breathe properly, tell him to count aloud as long as possible, without taking breath, and the next inspiration will naturally be full and deep. We can often bring out a very few râles, the demonstration of which over the pulmonary apices is very essential in the diagnosis of pulmonary tuberculosis, by auscultating the patient early in the morning, before he has expectorated the secretion accumulated during the night. Examination should be made with the patient in different positions. Râles can often be felt by the hand placed upon the chest.

Transmission of Râles.—Râles can also be heard by transmission at some distance from their place of origin. But their intensity ordinarily decreases so quickly that the determination of their origin rarely offers difficulty.

Oral Râles.—It frequently happens that râles may be heard at some distance when the patient breathes with his mouth open. In general these râles are so intense that they can often be heard at a distance even with the mouth shut. This transmission of râles through the mouth is particularly marked in the tracheal and pharyngeal râles of moribund patients. These râles owe their origin to the flooding of the bronchi, trachea, and pharynx by the fluid of the pulmonary edema, but, in the case both of moribund patients and of those afflicted with esophageal paralysis, may also be caused by failure to swallow the pharyngeal or laryngeal mucus. By auscultating and palpating the trachea and the larynx, it may be determined whether the râles arise here or in the depths of the lung. Owing to peculiar conditions for resonance, it occasionally happens that a deep area in the center of the lung produces oral râles which are not transmitted to the surface of the thorax. This symptom has a certain diagnostic significance.

MOIST OR BUBBLING RÂLES

The sound of moist or bubbling râles can be imitated through a glass tube into a vessel of water. The bubbles causes a characteristic crackling noise, which varies with the caliber of the tube and with the strength of the bubbling. A wide tube produces large bubbles, with a sound resembling that of *coarse bubbling râles*; a narrow tube causes fine bubbles, resembling the *small or fine bubbling râles*.

It is much easier to appreciate by the ear the difference between the fine and the coarse bubbling râles than it is to define them. *Coarse bubbling râles* are fewer in number, more intense, and of a lower pitch. *Fine bubbling râles* are more numerous, less intense, and of a higher pitch. This distinction does not, however, hold under all conditions, because accelerating the air-current in the tube mentioned above increases the number of the bubbles with the same character. On the other hand, holding the ear close to the tube will increase or diminish their intensity also without changing their character. Neither does the essential distinction depend on the pitch, for with many râles no distinct pitch can be perceived. Therefore, some other difference between coarse and fine râles must exist. The author imagines the difference to depend upon the size of the mass set in motion, i. e., in coarse râles the energy of the vibration is greater than in fine bubbling, because the moving mass is larger. And this influences not only the intensity of the vibrations, but, in consequence of the law of vibration, the tone itself. The coarse râles last longer. (See the Percussion-note, pp. 203 and 207.) If this explanation is correct, râles may be few in number, and, when they arise, very intense, and yet retain their fine bubbling character.

The term "bubbling" was employed because it was once supposed that moist râles arose from the bursting of air through a secretion. Of course, we know now that the contents of the bronchi are not sufficiently fluid nor abundant for such an explanation. It is supposed that the râles arise when membranes of secretion on the bronchial lumen, are stretched and then torn apart by the movement of the air and partly by the movement of the secretion. The *coarse bubbling râles* would therefore correspond to the *fine* to the thinner, layers of secretion. We always find a more or less extensive bronchial area; hence many different kinds of noises may give rise to the resultant "much bubbling." In single bronchi there be only isolated bubbles. The bubbling probably occurs only in quite rare cases, and when the lung is saturated with thin fluid, e. g., in pulmonary hemorrhage, pulmonary edema, or drowning.

Moist râles may be heard during expiration as well as during inspiration, although during inspiration they are almost always absent, possibly because the movement of the lung is then not sufficient to tear the secretion.

Very fine bubbling or moist râles are also named *crepitations* or *subcrepitations*, the latter from a certain similarity to the sound of *crepitation*. The choice of terms and the distinction between the two are thoroughly discussed upon p. 298 et seq.

A complete series of transitions exists between the

râles as one extreme and the fine subcrepitant râles as the other. The rattling tracheal or pharyngeal râle, generally heard in the moribund, even at a distance, belongs to the former variety. (See p. 293.) Fine moist râles more commonly originate in the fine tubes; coarse, in the larger tubes or in pathologic cavities. The former are generally more numerous because there are more fine tubes.

Moist râles arise only when the bronchi contain fluid or semifluid material; in most cases, therefore, they signify a bronchial catarrh, located in the large or small bronchi, according to the size of the râles. Fine moist râles have in general a more serious import, because a catarrh of the finer bronchi often leads to bronchopneumonia, and because such a catarrh frequently depends upon local changes of the pulmonary parenchyma (such as inflammatory consolidation, tuberculosis, or infarction). This is especially true if the fine moist râles be localized over a definite area of the lung. The obstinate persistence of such localized râles over the same area while the rest of the lung is permanently free, without any other signs, justifies the diagnosis of a serious process, either a tuberculous or a lobular pneumonic consolidation or an infarction. On the contrary, an ordinary innocent catarrh is much more diffused, because an otherwise healthy mucous membrane presents practically the same fostering soil throughout its entire extent. Coarse bubbling râles heard over areas where no large bronchi are to be found signify an especially serious affection, because they must arise either from pathologically dilated bronchi or from cavities. When heard over the apices, they are thus important signs of tuberculous cavities; when heard over the postero-inferior portions of the lungs, they more frequently depend upon bronchiectasis. Coarse moist râles are, however, frequently transmitted to quite a distance, a possibility which must be kept in mind when they are heard over areas somewhat remote from the roots of the lungs. Such a possibility may, however, be excluded if, at the same time, no coarse râles be heard over the larger bronchi. Moist râles of any size, when obstinately localized over a circumscribed area, point to a serious focal lesion of the lungs.

Mixed bubbling râles arise when the small as well as the large bronchi are affected. They may also arise from the larger bronchi and from pulmonary cavities without the smaller bronchi being affected, since, as has been mentioned, fine as well as coarse bubbling râles may be formed in the larger vessels and cavities.

Pulmonary hemorrhage and pulmonary edema, unless the larger bronchi are also flooded with fluid, present quite uniformly fine bubbling râles, which are frequently heard with both inspiration and expiration (continuous râles). The expectoration in these cases is ordinarily very foamy. If the larger air-passages be flooded also, coarse râles are mixed with the fine, and oral râles are often heard. (See p. 293.)

The sticky mucous secretion of an ordinary catarrhal bronchitis generally produces *dry* râles. Moist râles have a more serious significance; their appearance is associated with a fluid secretion deficient in mucus, *e. g.*, they are especially common in intense inflammatory processes of the mucous membrane or of the pulmonary tissue, in edema, stasis, and hypostasis. Moist râles constantly present over the apices of the lungs almost always mean tuberculosis. In such a case a thin fluid secretion, such as the moist râles suggest, signifies a marked purulent and destructive process.

DRY RÂLES (CRACKLING OR SNAPPING AND MUSICAL RÂLES)

Dry râles are produced by the movement of a viscid secretion. They have a more manifold character than moist râles. The latter are always composed of a more or less regular succession of separated noises. The former present either a quiet, isolated sound, a crackling which resembles to some extent a moist râle, or a musical sound (musical râles). The difficulty in mucus secretion probably accounts for the lack of regularity of the dry râles.

To explain the origin of the *crackling dry râle*, we suppose that the secretion of the mucous membrane of the bronchi is drawn out in the form of threads or bladder-like membranes by the air-current or by the movement of the lungs, and, by its tenacity, again sticks fast to another portion of the membrane without necessarily giving rise to another series of crackles. These differ very slightly in their origin from the moist râles. On account of its viscosity the secretion is probably on the membrane and then torn loose from the mucous membrane. In the case of dry râles this process is constantly repeated. Such a crackling râle tabulates the dry crackling râle as a subdivision of

Very possibly certain forms of crackling râles are not really dry, but depend upon the movement of secretion, but upon a jeune surface roughened and irregular from infiltration in the tuberculous apices.

Musical dry râles arise from the vibration of the mucous membrane which are drawn out across the bronchial lumen. They are produced by tension (but not torn away by the air-current), just like the reeds of a fiddle or the tongues of a pipe. Again, the walls of the bronchial tubes may be so swollen by inflammation as almost to occlude the tubes, forming a sort of whistle. Finally, the swelling of the mucous membrane may be situated at the angle between two communicating bronchi, acting like the tongue of a pipe. These various causes give rise to a diversity of musical râles, which sometimes resemble the purring of a cat, sometimes the tone of a violin, a harp, or a bass, sometimes the snoring of a sleeper, sometimes a shrill whistle. These various varieties may occur simultaneously. The deeper varieties arise in the larger bronchi; the higher, whistling varieties in the smaller.

The names crackling, sonorous, or sibilant râles, crackles, snores, or whistles—appropriately describe these various varieties.

When dry râles are obstinately localized at one point, they have the same serious significance as moist râles, even without the aid of percussion phenomena. (See pp. 294 and 295.) Persistence for a long time may be evidenced only by the sound heard at one apex.

Dry râles are often transmitted to a considerable distance. Musical râles are often appreciated by the palpating hand, especially in the case of pleuritic friction. (See p. 300.)

RESONANT (Consonating) AND NON-RESONANT (Non-consonating) RÂLES

Râles which arise in bronchi surrounded by solid, i. e., airless, tissue (consolidation, atelectasis) or in pathologic cavities, are transmitted, intensified, or modified by resonance, exactly as is pathologic bronchial breathing. (See p. 288 et seq.) They can become exceptionally sharp and distinct, and are called *resonant* or *consonating râles*, in distinction to the non-resonant râles heard over normal pulmonary parenchyma. The terminology is here somewhat confusing, for a dry musical râle must naturally be resonant, but is not modified by a resonance in the sense mentioned above. To avoid this confusion it is advisable to return to Skoda's term, *consonating râles*.

Dry musical râles (sonorous and sibilant), even when they arise in aerated pulmonary tissue, have so distinct and well recognized a musical character that conditions of resonance or consonance cannot alter them to any extent, and only a very skilled ear can distinguish any difference between consonating and non-consonating musical râles. On account of the marked preponderance of a ground-tone, consonance in such râles is evidenced more by an increased intensity than by any qualitative modification of the timber. Merely from the increase in intensity, we can draw no further conclusions. But moist and also *crackling râles* are very plainly affected by consonation. The entire effect is increased in intensity, and certain high partial tones are especially intensified by resonance. The result is difficult to describe clearly, but can easily be demonstrated upon an appropriate patient. In the discussion of bronchial breathing we showed that actual resonating phenomena do appear in the bronchi, and so there is no reason to doubt that a râle may resonate. But the better conduction through consolidated tissue is not alone sufficient to make the râles resonant; nor is loudness of any avail, for tracheal râles loud enough to be heard even at a distance show no trace of resonance. The resonating character depends, for the most part, on an admixture of the higher overtones. Certain types of stethoscopes will add a distinct resonance to râles. (See pp. 280 and 305.) A pulmonary cavity which presents a metallic note to percussion and an amphoric and metallic breathing to auscultation also furnishes consonating râles, with a metallic resonance.

The so-called metallic tinkle (*gutta cadens*), heard especially in tuberculous destruction of the lung, is apparently nothing but a metallic consonating crackling râle in a cavity (see, however, a similar sound with a different import, p. 302, *Pneumothorax*). After this discussion of its origin, the diagnostic significance of the consonating râle will require fewer words, for it should now be clear that the demonstration of the consonation of râles has exactly the same significance as the demonstration of pathologic bronchial breathing. And the author would emphasize to the beginner the importance of distinguishing consonance and non-consonance of the râles in the diagnosis of consolidations. If bronchial breathing, consonating râles, and dulness of the percussion-note were always present together over pulmonary consolidations, the presence of one or the other of these signs would be sufficient, and we could then dispense with the others. Unfortunately, it is not so simple; for, as we have already seen, bronchial breathing is very often heard without any dulness, and just as frequently there are consonating râles without bronchial breathing. Roughly, the con-

ditions essential for consonating râles and for bronchial râles; but either may be present alone, because the elements must be increased by resonance to exhibit character in the râles, on the one hand, and in the respiratory murmur on the other.

From a practical standpoint there is one thing to be remembered. A râle must possess a certain strength to be clearly heard; hence, with very superficial breathing we find that a consolidation or a cavity non-consonating râles, and bronchial râles, are transformed into consonating râles. It is often very difficult to demonstrate in quite sick patients because the superficial breathing characteristic of this stage is strong enough to produce plain bronchial breathing. In some cases certain ones may be consonating and other ones may be non-consonating because parts of the mixed breathing murmur are not strong enough to bring out the consonation.

CREPITANT RÂLES OR CREPITATIONS

During the first stage of croupous pneumonia, when the lung is in the state of engorgement, when the percussion is still full of air, when percussion discloses no dulness, when auscultation shows no bronchial breathing, there is to be heard in the affected part of the lung the so-called *crepitant* or *crepitatio* (crepitatio indux). A similar noise (crepitatio redi) is heard during the resolution stage of pneumonia when the lung again becomes aerated. This characteristic sound is also heard in *croupous* and *catarrhal pulmonary inflammation*, in *tuberculous infiltration*, in *hemorrhagic infarctions*, in *pulmonary edema*. In most cases only audible *crepitation* possesses a certain acoustic similarity to râle (subcrepitant), and can be very well imitated by rubbing the fingers, near the ear.

Formerly, crepitation was considered to be a true râle, arising when the air-current set into motion flows through the finest bronchi and alveoli. But this supposition has long since taken the first place, because we can reproduce crepitation by rubbing between the fingers the absolutely dry lung. It is again because in perfectly healthy individuals, with the exception of the alveoli or bronchi, crepitation is sometimes heard even when the patient has been breathing superficially for a long time and then takes a deep breath. The fact that it is heard only with inspiration is a strong argument against its origin from the movement of secretion. It is universally conceded that crepitation does not arise from the movement of secretion, nor, as was earlier supposed, as a consequence of microscopic explosions of air-bubbles in the fluid content of the lung, but from the tearing apart of the approximated alveoli by the inspiratory stream.¹ In pulmonary engorgement or in the stage of pulmonary edema we can well imagine that the

¹ [Prof. Sahli has entirely disregarded one theory of the origin of crepitation, that it is in reality a very fine pleural friction rub and does not arise from the lung. So good an authority as Osler says, "Whether this is a true râle or is produced in the air-cells and finer bronchi is still an open question."]

ing and soaking of the alveolar walls would approximate them, and the presence of some fluid secretion or exudation in the alveoli would only favor each expiratory adhesion. Still, fluid plays here a secondary rôle. In pulmonary edema, if the transudation increase, genuine fine bubbling râles become gradually associated with crepitation, and later on, when the fluid reaches the greater bronchi, even coarse moist râles are developed. An excellent opportunity is thus afforded to study the difference between crepitation and the fine moist, or so-called subcrepitant, râles. They are easily distinguished by remembering that the former occurs during inspiration and possesses a resonating character.

When associated with bronchial breathing, crepitation points to the beginning of a consolidation, and has, therefore, a serious significance. On the contrary, however, the crepitatio redux at the termination of a pneumonia is a longed-for sign of beginning resolution, and a demonstration that the alveoli have once more become permeable to air. Crepitation may in certain cases be heard over some spot or other of the chest during the entire course of croupous pneumonia, because this disease almost never develops simultaneously at all points.

In making a diagnosis, the existence of the above-mentioned physiologic crepitant râles at the borders of the lung must be remembered. When there is but little need of air, the lungs are not freely expanded, so that the alveoli at the borders of the lung may become empty through compression. If, then, the patient be made to take several full breaths, the air rushing into the collapsed alveoli may cause crepitation. These physiologic crepitant râles appear only near the borders of the lungs, usually occur symmetrically on both sides, especially in front, and disappear after a few deep breaths. They may be further differentiated by the absence of any other abnormal signs at the spot in question.

Actual crepitation may exceptionally be heard with expiration, probably depending upon the fact that under usual conditions some of the alveoli become filled with air during expiration instead of during inspiration. This is simple enough to understand if we suppose that, in consequence of adhesions or of partial rigidity from small areas of consolidation, one portion of the lung does not breathe so well as an adjoining part, and that the part breathing well may, on account of some obstacle opposing its emptying (secretion or swelling of the mucous membrane), sometimes pump the expiratory air into the part breathing poorly. The latter will then be distended while the rest of the lung expires, thus giving rise to a crepitation which is expiratory in relation to the general respiration, but inspiratory in relation to the affected part itself. In lobular consolidations at the sharp pulmonary edges the author has not infrequently found this expiratory crepitation.

CARDIOPNEUMATIC RÂLES (Cardiac Râles and Cardiac Crepitation)

Before concluding the discussion of the ordinary râles occasioned by respiratory movements, we should mention the fact that in rare cases with coexistent catarrh of the bronchi, râles may be produced by the movements of the heart itself. These are due in part to the direct mechanical vibration of the adjoining portions of the lung; in part, however, to the systolic and diastolic variations of intrathoracic pressure from alterations in cardiac volume (auxo- and meiocardia). Such variations cause real respiratory excursions of the adjoining pulmonary

that it can be just as plainly heard during expiration as during inspiration, and that it is more jerky than the crepitation. Friction sounds heard over the precordia, which originate from the pleura, from the pericardium, or from the sharp pulmonary edge overlapping the heart, may be synchronous with the cardiac action as well as with the breathing. They are called *pleuropericardial*, *pseudopericardial*, or *extra-pericardial friction sounds*, and are liable to be confused with true pericardial rubs. (See Pericardial Friction Sound for Diagnosis.)

In pleurisy with effusion, the friction sound disappears, because the layer of fluid prevents the two pleural surfaces from touching and rubbing. The rub may persist, however, along the edge of dullness, rather more commonly in front than behind. Such a persistence proves that the two pleural surfaces touch and rub against each other somewhere above or below the adhesions, encapsulating the fluid exudate. The reappearance of a rub within the boundaries of the dullness is a favorable sign, because it shows that the fluid is diminishing and the pleural surfaces are again in contact. The dullness may then be due, at least in part, to thick layers of fibrin. Loud friction sounds may, of course, be transmitted some distance from their place of origin; but if they be plainly felt by the palpating hand over the area where they are heard loudest, it is pretty good evidence that they arise very near by.

RESPIRATORY MURMURS IN INTERSTITIAL PULMONARY EMPHYSEMA

When air from within the lung is forced into the interstitial pulmonary connective tissue by the rupture of one or more alveolar walls, bubbling sounds and sometimes murmurs are produced by each respiratory excursion. These sounds generally recall coarse or mixed moist râles, and, for the most part, are resonant in character. The resonance, which may assume even a metallic character, probably depends upon the resonance in the cavities formed by the bubbles. Sometimes these sounds simulate the familiar emphysematous crackling of the skin (see p. 57), but they are too coarse to be confused with crepitation (p. 298 et seq.). When large emphysematous bubbles are situated beneath the pleura, they may sometimes decidedly weaken the respiratory murmur. Interstitial emphysema may be present at any spot; it may spread over the entire lung, and from there in the mediastinum and into the subcutaneous connective tissue. Sometimes the diagnosis of interstitial pulmonary emphysema will be first securely established and the confusion with râles prevented by the demonstration of the precordial murmur of emphysema, and of the characteristic crackling of the skin.

NOISES AUDIBLE IN PNEUMOTHORAX

PLEURAL SPLASHING (*Succussio Hippocratica*)

Hippocrates first described the characteristic splashing noise produced by shaking a patient with sero- or pyopneumothorax. The noise is similar to that made by shaking a large flask half filled with water, and arises in the same way. Sometimes it is audible at a distance; sometimes only to be heard when the examiner places his ear against the chest. The patient himself frequently notices the noise during all violent movements. The splashing sometimes presents a distinctly metallic timbre, according to the shape and size of the pneumothorax cavity and to the tension of the contained air.

Similar succussion noises may evidently arise in any other physiologic or pathologic body cavity containing both air and fluid; for example, when air is contained in the pericardium or in the peritoneum with a fluid effusion. It is also occasionally heard in a large pulmonary cavity,

and quite frequently in perfectly healthy people with large amounts of fluid and air. In order to differentiate succussion in pneumothorax from these peculiarly from the last-mentioned physiologic sound contents, we must utilize the results of other means and endeavor to localize the origin of the splash as possible by the proximity of the ear, and also by with a filled and a fasting stomach. Frequently the examiner can appreciate, with his hand applied to a distinct blow of the fluid wave within the pleural space of the shaking.

WATER-WHISTLE NOISE (Pulmonary Fistula)

This is a characteristic gurgling which often sounds like that of a coarse bubbling r le. It is occasionally heard over the air or the fluid is removed by aspiration, and so the atmospheric pressure in the pleural cavity. In a valvular pneumothorax will arise as soon as the pressure within the pleural cavity falls to that of the atmospheric pressure; then air immediately escapes through the pulmonary fistula. If this fistulous opening be situated beneath the surface of the lung the noise is produced by the rising of the air-bubbles. Of the character and of its mode of origin, Unverricht called it a *Riegel* noise, and Riegel called it a pulmonary fistula noise. The same noise can be heard without aspiration if in a patient with a pyopneumothorax, air be sucked in with inspiration during the expiration, or, again, if with coughing air be squeezed out of the lung through the pneumothorax which opens through the thoracic wall but which also has a pulmonary fistula. The sign is of some value in recognizing the occurrence of a pulmonary fistula.

THE NOISE OF FALLING DROPS (METALLIC TINKLING NOISE OF THE THORAX)

In pulmonary tuberculosis, as we have seen upon page 298, the noise of falling drops is always to be considered as a simple phenomenon, but in pyopneumothorax, on the contrary, actual falling drops are possible. When such a patient changes from the recumbent to the upright position it is possible that the shaggy prominences of the pleura covered with fluid previously moistened, free themselves from fluid drop by produce a metallic dropping noise.

AUSCULTATION OF THE VOICE SOUNDS OVER THE CHEST (BRONCHOPHONY)

Transmission of the voice sounds from the larynx through the lung to the chest surface is subject, under certain conditions, to the laws which govern the transmission of respiratory murmur. The voice sounds are there heard in the areas where we hear physiologic bronchial breathing, namely, in the axill hilum of the lung between the shoulder-blades, and in the upper part of the sternum. But even in these regions, under certain conditions, no distinct articulation is heard, although when the voice is strong, sometimes almost fluttering sound is heard. The transmission of the voice is known as *physiologic bronchophony*. Under conditions to which it is due are similar to those which govern the transmission of bronchial breathing. At best the voice cannot be heard distinctly but sounds as if some one were talking at some distance. The whispered voice is heard more distinctly. Pronounced bronchophony will

dividual sounds and the rhythm of syllables. Very faint bronchophony is known as "bronchial whispering or lisping."¹ Physiologic bronchophony decreases rapidly from the region of the larger bronchi toward the peripheral portions of the lung, so that here only an indistinct humming can be detected.

Pathologic bronchophony is similar, acoustically, to the physiologic form. It is due to the same conditions and is subject to the same laws as pathologic bronchial breathing. It is heard over areas of compressed or consolidated lung with patent bronchi, over bronchiectases, and over pulmonary cavities. Bronchophony may acquire a metallic sound over cavities. Pathologic bronchophony, like bronchial breathing, owes its origin partly to better conduction of sound by bronchi which are surrounded by a consolidated area and partly to resonance. Physiologic bronchophony varies in different individuals; hence, in order to detect any pathologic change, it is usually advisable to compare symmetric portions of the chest. It should, however, be remembered that physiologic bronchophony is ordinarily louder on the right side, just as is physiologic bronchial breathing. Both the spoken and the whispered voice should be tested, and the ear which is not used for auscultation should be closed, so as to avoid any sound transmission through the air. Pathologic bronchophony has exactly the same diagnostic significance as consonating râles and pathologic bronchial breathing (see above). All these signs, in virtue of their common origin and uniform significance, may be included in the term "consonating phenomena." Each one should, however, be looked for, because in spite of their uniform cause and significance, any one of the three may be imperfectly developed; bronchophony, especially for the whispered voice [whispered bronchophony.—Ed.] may be heard over a consolidated area, although bronchial breathing is indistinct. If deep breathing be painful or impossible, so that no bronchial breathing can be detected, the demonstration of bronchophony may be of great value.

Extreme bronchophony, or *pectoriloquy*, and *egophony*, a form of bronchophony with a peculiar bleating quality, are sometimes considered as distinct and separate phenomena. But the author does not consider it justifiable to attribute these signs to different conditions, because the various types of bronchophony blend in such a manner as to be indistinguishable one from the other. Neither does he consider it justifiable to attribute any special diagnostic significance to pectoriloquy as a sign of cavities, nor to egophony as a sign of a pulmonary compression which is sufficient to cause flattening of the bronchi. Pectoriloquy may be so decided over a consolidated area that the examiner can appreciate the articulation although he cannot actually distinguish the word. Egophony may also be audible over such an area. All sorts of theories have been suggested to explain the occurrence of the bleating sound in egophony, but none of them has satisfied the conditions from the standpoint of physics. In any case egophony is simply a quantitative increase of ordinary bronchophony and, therefore, cannot depend upon a compression of the bronchi. If the breathing sound amphoric, and if the percussion-note be metallic, the bronchophony is apt to assume either an amphoric or a metallic timbre. By examining for bronchophony with the naked ear, the

¹[The term "bronchial whisper" should not be confused with "whispered bronchophony."—Ed.]

ocal fremitus can be accurately determined at the same time. The skin of the ear can appreciate the vibration even more delicately than can the hand, possibly owing to the vibration of the cranial bones.

VARIOUS ERRORS IN PULMONARY AUSCULTATION¹

An expert finds auscultation of the lungs much more difficult than auscultation of the heart, and to a beginner the former is especially so on account of many possible errors. First of all, there is the *hair crepitation*, caused by the displacement of the hairs under the stethoscope with respiration. This occurs in persons with even a moderate growth of hair on the chest. The crepitations are synchronous with the respiratory movements, and an expert will quickly recognize the sound is just as marked during inspiration as during expiration, and that it is intensified by a careless use of the stethoscope. This source of error may be so annoying that it is necessary to wet the chest thoroughly with water, soap solution, or oil. If the hairs be too thick, the procedure to be effective, the spot should be shaved.

Muscle sounds may also lead to error. In auscultating the apices of the lungs, sounds produced in the trapezius as it takes part in the respiratory excursion may be very disturbing. They may simulate crackles, rattling or even râles. It is important to be able to recognize these sounds, so as to avoid error. Muscle sounds may also be produced by a fibrillary contraction of muscles, e. g., "shivering," due to the nervousness of the examination. These sounds may be appreciated by observing that shivering is apparent to the eye. Such sounds may be distinguished from the respiratory murmur by asking the patient to hold his breath; if they persist, they are not respiratory. Besides these sounds there is a so-called "passive variety," which may be produced by the displacement of bundles of muscle-fibers under the stethoscope by light movements of the instrument or by the respiratory excursion of the chest itself. These sounds may be recognized by intentionally moving the stethoscope, and so reproducing the sounds when the patient is not breathing. Again, such sounds may be heard when examining with the naked ear or when very lightly touching the stethoscope. Other sounds originate from similar causes, as, for instance, that produced by pressing the stethoscope against the subcutaneous fat in the female breast. These sounds frequently simulate crackles very closely. They disappear when the stethoscope is held properly, and reappear when a little pressure is exerted. They also disappear when the patient stops breathing.

Unfavorable positions of the body which are difficult of access are also often liable to produce *typical friction sounds* artificially. If the patient be in an uncomfortable position, and if his stethoscope is not accurately or firmly applied, so that the patient's skin moves with respiration. Hence, it is a good plan for him to stop his examination by listening with the naked ear or after adjusting his stethoscope. If the skin be greasy or sweaty, it should be rubbed clean with a dry towel.

¹ This section appeared in the first edition of this work in 1894, long before the publication of the work on the same subject, and, therefore, is in no way based upon Treupel's

There are a great many other opportunities for producing extraneous sounds and so confusing the examiner. We might emphasize the necessity of persuading patients that their chests should be entirely uncovered for a proper examination, that they should not scratch themselves during the examination, and should remain absolutely quiet. It is perfectly useless to attempt an examination, particularly of the apices of the lungs, unless the patient's upper chest is entirely uncovered. A patient's false modesty, his fear of catching cold, or the examiner's laziness—none of these reasons can possibly excuse a careless examination.

It is desirable for every physician to accustom himself thoroughly to the use of one form of stethoscope. Even if he be accustomed to a poor instrument, he will make much better use of it than at his first attempts with a better one. Stethoscopes differ decidedly in their reproduction of consonation, *i. e.*, bronchial phenomena. The popular hard-rubber stethoscopes, for example, with comparatively long, open bells and thin, smooth walls, increase the resonance very decidedly. Mixed breathing through one of these instruments sounds much more bronchial than through a cylindric wooden stethoscope. *Râles* assume a more consonating character when heard through the former, a fact which the author considers a practical proof that consonating *râles* are produced by resonance and consonation.¹

Another source of error in auscultating the chest may be mentioned. If the stethoscope bell be carelessly applied to the chest-wall, so that part of its edge does not rest there firmly, but is slightly elevated, thus allowing the air free entrance to, and exit from, the bell, the examiner will frequently hear a very good imitation of bronchial breathing. The sound is, of course, due to resonance. Probably the noise of the patient breathing through his mouth is transmitted and exaggerated by the open bell. It is quite similar to the sound we hear when we place a large sea-shell with its opening near the ear; when external sounds ordinarily unnoticeable are so much exaggerated by resonance that children frequently imagine they hear the roaring of the sea.

AUSCULTATION OF THE HEART

We almost always need a stethoscope to auscultate the heart properly, because, for the sake of diagnosis, we wish not only to appreciate the sounds, but also to localize them as accurately as possible. We often need to auscultate the heart, both in the recumbent and in the erect posture, and sometimes in other postures. Hence, it is a good routine to auscultate every patient's heart, both while he is lying down and while he is sitting or standing up. (See Mitral Insufficiency and Aortic Insufficiency.)

¹ [The use of the single-barrel stethoscope preferred by Prof. Sahli is not common among the profession in America. Undoubtedly, many of his reasons for this preference are well founded; but a good binaural stethoscope will transmit the sounds quite as plainly, always provided that the examiner is thoroughly accustomed to the resonance of his own instrument. So many different stethoscopes have been advised by different authorities that it seems unnecessary to recommend any special type.—ED.]

NORMAL AUSCULTATION SIGNS OVER THE HEART

The only sounds we hear over a healthy individual's heart are the so-called "*heart tones*." The word "*tone*" is not used here in strict acoustic sense, because the sounds heard are more than only quite rarely possess a distinctly recognized quality. Some authors call normal heart tones "*bruits normaux*" and the English have retained the term "*tone*" in spite of its inaccuracy, and have reserved the word "*geräusch*" for certain pathologic sounds to be discussed later (see the distinction between tones and murmurs.)

We normally hear two heart tones over the heart. With increased cardiac activity they may often be heard from the cardiac region. They follow each other in a regular rhythm. They can be imitated by pronouncing "dupp," or by tapping a closed book quite lightly with the fingers. A short pause exists between the first and a longer pause ensues before another first tone. The first tone (the so-called systolic tone) is synchronous with the beginning of the heart sound, felt in the fifth intercostal space, i. e., the beginning of the second is synchronous with the beginning of the heart sound, before called the diastolic tone.

Physiologists have proved that each heart tone is composed of several factors, and that the reason why at any point of time two tones are heard is because all cardiac tones are either systolic or diastolic. In other words, all systolic tones are massed together and all diastolic tones. In reality, six different tones are heard, four systolic and two diastolic.

The four systolic tones originate:

1. Over the left ventricle, at the mitral valve
2. Over the right ventricle, at the tricuspid valve
3. Over the beginning of the aorta.
4. Over the beginning of the pulmonary artery.

The two diastolic tones originate:

5. Over the aortic semilunar valves.
6. Over the pulmonary semilunar valves.

Hence, no diastolic tone originates over the heart valves, i. e., over the ventricles.

It has been clearly understood for years that the heart sound is produced only by diastolic tension of the heart muscle. The origin of the systolic tones has, however, baffled the physician for a long time. Without going into the historic presentation of the present theory, which has apparently stood the test of clinical observation, will be briefly mentioned. The heart sound is heard at the apex, originates, according to the present theory, from the systolic tension of the auriculoventricular valves closed at the end of diastole. This view is supported by many observations. In addition, experiments upon the blood vessel have shown that the muscular sound of the heart muscle also produces the systolic tone. The expression "*murmur*" must not be construed in the same way as when that is heard in the skeletal muscles. The muscle sound of a skeletal muscle depends directly upon the number of in-

which together produce the condition of tetanus. The contraction of the heart is, however, single and not tetanic; hence, its muscular sound is very different from the skeletal muscle sound. The muscular sound of the heart is in reality a vibratory phenomenon caused by the sudden systolic tension of the heart; in other words, a systolic tension tone, of exactly the same character as, and coincident in time with, the tension tones produced at the auriculoventricular valves and over the large arteries (aorta, pulmonary artery). This conception, therefore, means that all systolic tones of the heart are identical in character and are due to tension of its walls, including its valves. The systolic tones over the aorta and pulmonary artery are referable to the systolic tension of the still closed semilunar valves. They are produced by the sudden increase in intracardiac pressure at the beginning of the systole.

As there is no reason to separate the tension tone at the great vessels—in so far as it occurs during closure time—from the tones of the auriculoventricular valves and the heart-wall tone, the six tones given in the foregoing scheme can be well reduced to four, 1 and 3, and 2 and 4 being united under the names of left and right intracardiac tension tones.

The supposition that the systolic tones over the great vessels originate in a similar way to the first tones over the ventricles and auriculoventricular valves, and that they all are due to intracardiac tension during closure time, is supported by the fact that they are all coincident in time, provided the tones over the vessels are auscultated very close to the heart. Still, the older theory that the systolic tone of the vessels is produced by the sudden forcing of the blood into them during systole is, to a certain extent, justifiable in as far as a second component of the first tone can very often be detected over the vessels as the blood is entering them, *i. e.*, in the beginning of the expulsion time. (See p. 322.)

Clinically, it has been quite generally accepted that the systolic tones originate not only at the auriculoventricular valves and over the ventricles, but also at the great vessels (aorta and pulmonary artery). This opinion has been attacked upon physiologic grounds. Nevertheless, the author considers that the clinical view is unequivocally supported by cases of mitral and tricuspid insufficiency which furnish systolic tones over the auscultation area of the great vessels, while no such tones can be made out over the ventricles. Such cases are not very rare. These systolic tones may then depend upon the intracardiac tension tone of the closure time or upon "the expulsion tone" in the great vessels or upon both together. The last alone can be positively demonstrated by the exhibition of a reduplication of the tone.

In the interpretation of the pathologic changes of the systolic tones which originate over the ventricles, the clinician has thus far concerned himself almost exclusively with that part of the tone which originates in the valves. Hence systolic tones which are heard over the left ventricle are commonly called "mitral tones," those heard over the right ventricle, "tricuspid tones." The so-called *muscular tone* has thus far proved of little diagnostic significance because we cannot readily distinguish it from the proper valvular tones. Certain impurities in the first tone, usually referable to the auriculoventricular valves, may, however, be caused by the muscular tone on account of the irregularities in the systolic tension of the heart muscle (*e. g.*, in fibrinous myocarditis). Perhaps finer methods of examination may be devised, so that we may be able to utilize the muscular tones in the diagnosis of diseases of the heart muscle. (See p. 321.)

empirically the points at which each valve tone can be best auscultated separately.

The following relations between the sites of the valves (Luschka) and their respective auscultation points have been demonstrated by extensive experience:

The *mitral valve* is situated beneath the junction of the third left costal cartilage with the sternum; its *tone* is heard best over the apex-beat.

The *tricuspid valve* is situated halfway between the points where the left third and right fifth costal cartilages join the sternum. Its *tone* is heard best over the lower end of the sternum.

The *pulmonary valve* is situated in the second intercostal space, somewhat to the left of the edge of the sternum. Its *tone* is best heard at this point.

The *aortic valve* is situated about the middle of the sternum, at the level of the third costal cartilage. Its *tone* is best heard in the second right intercostal space, near the edge of the sternum.

The *mitral valve tone* is best heard at the apex, because the valve itself is overlapped by the lungs and by the right ventricle with the tricuspid valve, while at the apex the overlying lung tissue is very thin, and the left ventricle, in which the sound is produced, is not covered there by the right ventricle, or, at least, to a less degree than farther above. Further, the eccentric situation of the apex prevents the other heart tones from being so readily transmitted there.

The above statements explain why the rhythm of the heart tones differs at different points over the heart. The author will state the facts, and then attempt to explain them. Over the auscultation points for the aorta and pulmonary artery and in the vicinity, the heart tones exhibit an iambic rhythm (lubb-dúpp, lubb-dúpp).

Over the lower part of the sternum, however, and as far as the apex-beat, *i. e.*, over the auscultation points for the auriculoventricular valves (the ventricles), the heart tones produce a trochee (lúbb-dupp, lúbb-dupp).

This may be explained as follows: No diastolic tone is produced at the auscultation points for the auriculoventricular valves. The second tone is heard only by transmission from the aorta and pulmonary artery; consequently, it is proportionately diminished. Hence, the accent upon the first tone (trochéé). The conditions are different over the great vessels, where both a first and a second tone are produced. Naturally, the first tone is relatively weak because it is produced by a moderate increase in pressure upon the roots of the great arteries acting against considerable arterial pressure at the beginning or closure time of systole. On the other hand, the second tone is much stronger and accentuated because it is produced by the rapid and forcible closure of the elastic semilunar valves acting under the pressure of the aorta and pulmonary arteries. This accounts for the iambic rhythm heard over the great vessels.

DISTINCTION BETWEEN SYSTOLE AND DIASTOLE IN AUSCULTATION

One of the most important requisites for the diagnosis of cardiac lesions is the ability to distinguish the systolic from the diastolic phase of the heart's action; in other words, to recognize accurately the systolic

and diastolic tones. An experienced clinician is especially difficult under normal conditions, because of the tones. The diastolic tone is accentuated and the systolic tone is accentuated at the apex valve.

The sequence of the heart tones at the base auscultation points for the auriculoventricular following scheme (where the beginning of systole is marked by a vertical line):

Great vessels: $\begin{array}{c} | \\ \hline S \end{array} \quad \overline{D} \quad \begin{array}{c} | \\ \hline S \end{array} \quad \overline{D}$

Auriculoventricular valves: $\begin{array}{c} | \\ \hline S \end{array} \quad \overline{D} \quad \begin{array}{c} | \\ \hline S \end{array} \quad \overline{D}$

Some cases, however, furnish exceptions to this method. In that the first and second sounds are not distinct. Under such circumstances the peculiar method furnishes the most efficient means of differentiation. Clinical experience has proved that systole is therefore the systolic tone is the one preceded by silence. In other words, if the heart tones are heard according to the interval of silence, and practiced instinctively, the first tone of each pair will be the systolic and the second tone the diastolic. In the following scheme the two heart tones are equally accented, but distinguished by the relative lengths of the pauses between them.

$\begin{array}{c} | \\ \hline S \end{array} \quad \overline{D} \quad \begin{array}{c} | \\ \hline S \end{array} \quad \overline{D}$

Even this method may be unavailable, because the heart tones are sometimes equal in length (pendulum rhythm), which usually depends upon palpating the apex-beat. The method provided the heart action be not too rapid and sufficiently forcible. If, however, the heart action is very rapid, between the beginning of systole and diastole is the sensation of touch with the perception of so little difference.

Comparing the heart tones with the carotid pulse action is rapid, even less reliable than comparing the heart tones with the apex-beat, as the apex-beat is synchronous with the carotid pulse corresponds more accurately to the heart action.

Systole can never be determined from the heart action if the heart action be very slow. If rapid, the radial pulse is usually second, according to Landois), and so coincides more with diastole than with systole. Students should, therefore, be warned.

Systole and diastole can, as a rule, be readily distinguished by these methods, but under certain pathologic conditions heart action is very rapid, especially if it be irregular, the distinction may be extremely difficult. Decision must be deferred in such cases until the heart action has quieted down, or at rest, or with the aid of drugs (digitalis).

In many heart lesions systole may be deter-

characterized pathologic heart murmurs, particularly those which are accentuated toward their termination and which occur only immediately before systole—that is, are presystolic. (See p. 334 et seq.)

In the above description the author has enumerated the different methods for recognizing the phases of the heart's action in the order of their practicability. The most desirable and the most commonly employed in practice is the determination of systole by the accentuation of the tones and their relation to the pause. Students should practise this method assiduously, and not form the habit of determining systole by feeling the carotid pulse, or, worse still, the radial pulse. The method recommended affords excellent practice in training the ear, and is of great importance to physicians who have never studied music.

THE GRAPHIC REGISTRATION OF THE HEART TONES AND THE CHRONOSCOPIC DETERMINATION OF THE LENGTH OF SYSTOLE

Hürthle, by means of the telephone, and Einthoven, by the string galvanometer, have both succeeded in registering the heart tones automatically. But in each method the apparatus is too complicated and expensive, and the procedure too tedious and difficult for clinical use. It is exceedingly desirable to obtain the same result by a simpler method, since the graphic registration of the heart tones is of the greatest clinical interest for the determination of the time of systole and diastole. Martius, so far as the author knows, was the first to employ auscultation for this purpose. By recording manually the results obtained by the sense of hearing, he has obtained important data for the interpretation of the normal cardiogram (see p. 365); but unless it has escaped the author, his method has not yet been adopted clinically. The author has experimented with this method with two purposes in view: (1) To obtain the means of interpreting irregular sphygmograms, since the registration of the heart tones gives the rate of the heart action (particularly important in the case of extra systoles); and (2) to determine the length of systole as an aid in the diagnosis of changes in the heart function.

In this case the point is the determination of the *interval* between the first and second heart tone, or the registration of *both* heart tones.

The author in general made use of the simplified Jaquet's sphygmocardiograph (see p. 126), recording the radial pulse directly, where this was demanded by the purposes of experiment, and simultaneously marking on the same paper, by means of the pneumatic writing apparatus, the heart tones as heard on auscultation. For this purpose the writing apparatus was connected with a rather thick-walled rubber tube, closed at the free end. This tube was struck by the finger, following the rhythm of the heart action. At each beat a mark was, therefore, made on the paper. The author used the rubber tube instead of the tambour, which Martius employed, because after the first stroke the drum membrane was likely not to come back into position in time for the second, in case the two tones were close together, so that a purely mechanical cause was apt to effect a delay in the registration of the second tone. Although this difficulty was obviated by the use of the rubber tube, another, already pointed out by Martius, remained—the physiologic reaction time of the experimenter. The time required to appreciate the heart tone and to move the finger necessarily delayed the registration of the tone beyond its actual time. Martius showed that where the heart action is perfectly regular, this error is eliminated, since the ear of the experimenter becomes so accustomed to the rhythm that to a certain extent he gives the stroke at, and not after, the moment of the heart-beat. The author believes the correct explanation to be rather that the experimenter gradually comes to appreciate the length of time between the two beats and registers this interval rather than the exact moments of the beats themselves. For, from the moment when one grasps the length of the interval as an entity, it is no longer a question of the reaction time, but merely of the rhythm. But even then, as Martius has pointed out, results corresponding to those obtained by the *exact* marking of the tones are confined to cases where the heart action is absolutely and mathematically regular—and this is not the case, even under physiologic conditions. Strictly speaking, then, this procedure does not give an exact registration of the tones, especially in pathologic cases with irregular heart action. To be sure, it might possibly be conceivable that each experimenter after great experience, if he controlled his results by comparing them with the cardiogram, which, at least in

simple cases, gives directly the time of the second heart tone, might be able to determine his personal equation and make allowance for it in the curve. But the difficulties interfere only with registering the exact moment of the first heart tone

Radial pulse = 43.
Over the heart = 86.

Both radial pulse =
heart =

Fig. 153 —Pseudobradycardia caused by extra systoles.¹ In the first curve, it is a case of a regular sequence of extra systoles. In the second curve, it is a case of a regular sequence of extra systoles. In the second curve, the normal rhythm transpires until extra systoles recur. The apparent series of unshortened bigeminal pulses with compensatory pauses and

They do not militate against correct results for either of the above: (1) the determination of the rate of the heart action from the first heart tone, and (2) the determination of the rate of the heart action from the second heart tone.

Fig. 154.—Pocket chronoscope (exact size)

the first case only the numerical registration, not the exact time, is required. (See results of such an experiment in Fig. 153.)

¹This curve was registered by striking a drum instead of a watch. The marks are too high for accuracy in marking the time.

In the second case—the determination of the duration of systole—the interval between the two tones is independent of the reaction time, since the latter delays equally the registration of each tone. The author, therefore, believes that valuable results concerning the length of systole may be obtained by this method, especially as by its means he has already determined that very considerable differences in this regard occur, *e. g.*, the prolonged time of systole in the so-called pendulum rhythm.

It is obvious that this method may be modified by discarding the graphic apparatus and simply registering the time of the beats on a watch held in the hand. For this purpose a stop-watch or chronoscope, giving fractions of a second, is necessary. Peyer, Favanger & Co. (Neuchâtel, Switzerland) have furnished the author with a suitable instrument.

Fig. 155.—A part of the inner mechanism of the pocket chronoscope (exact size).

The large hand makes its circuit in one second; the small hand, in one minute. The time may, therefore, be read to $\frac{1}{120}$ of a second. Before using the watch, both hands must be brought to the 00 mark. By pressing at *m* the works are set in motion, as evidenced by the sound, but the hands do not move. At the beginning of the period of time to be measured the hands are set in motion by a second push at *m*, and at the end stopped in the same manner. After the time has been read off, a fourth push at *m* brings the hands back to 00. In order to secure the necessary uniformity of movement, the very delicate regulator of the Hipp's chronoscope is used, instead of that of the ordinary watch.

An elastic steel tongue (*d*, Fig. 155), when struck, vibrates like a tuning-fork, thus producing the bugle-pitched humming sound heard when the works are set in motion. This engages with the brake wheel, *b*, and is set in vibration when the latter revolves. The rate of vibration of *d* governs the velocity of *b*, as, at each vibration of

plish the necessary transformation of velocity. a'' engages with b , which, therefore, governs the rapidity of the wheels, according to the rate of vibration of d . The axis of one of the wheels pierces the ground-plate of the watch in a direction perpendicular to the plane of the figure, and sets in motion the wheels that turn the hands. These are invisible in the diagram, being located on the other side of the ground-plate. The mechanism by means of which the four pushes at m accomplish the four results above described (setting the works in motion, setting the hands in motion, stopping the hands, bringing hands to 00 point) is not visible in Fig. 154, being situated on the other side of the ground-plate. It consists of an arrangement of levers similar to those of the ordinary stop-watch. Each pressure at m turns a swivel, which has four arms or sectors at right angles to each other, through a certain angle around its axis. The different positions thus occupied by the sectors correspond to the different positions of the levers. The first push, by displacing a spring, releases the brake wheel b , and so sets the works in motion. The second push inserts a movable connecting wheel between the moving works and the wheels that move the hands, thus immediately setting the latter in motion. The third push releases this connection and so stops the hands instantaneously, as their inertia is very slight. The fourth push, by means of an eccentric disc (the so-called "heart") brings the hands back to the 00 mark. The only part of this whole mechanism visible in Fig. 155 is the spring n , which sets free or arrests the wheel b as the spring p is shoved by the pin o . As the entire mechanism is of purely technical interest, it need not be described further here.

Fig. 157.—Diagram representing the top view of the apparatus, with the four buttons (exact size).

It is important for exact measurements that the works be set running before the time to be measured begins, in order that their initial inertia may have been overcome and they may be running at full speed before the hands are set in motion. The watch must always be fully wound and the observations be made only during the first three-quarters of a minute. After the small hand points to 45, the watch must be completely wound again and the hands set at 00. Otherwise, sufficient accuracy is not guaranteed.

When the time must be read accurately to within $\frac{1}{100}$ of a second, as in estimating the duration of systole, the time required to press at m causes a considerable error, so that the instrument must be modified by an arrangement to accomplish this automatically. Such an arrangement is shown in Fig. 116. By its means the finger of the experimenter, instead of completing the pressure at m , merely touches lightly the buttons 3 and 4 and the motion is completed by a previously stretched spring. The principle is similar to that of a hair trigger.

Fig. 156 shows the watch inserted in a nickel case. When the case is opened, the mechanism is visible and easily understood. As has been said, m must be pressed four times in measuring any given interval of time, as follows: (1) To bring the hands to 00; (2) to set the works in motion; (3) to start the hands; (4) to stop the hands. To accomplish these four ends, four buttons, 1, 2, 3, 4, are provided, as seen in the cross-section (Fig. 157).

In Fig. 157, 3 is shown behind 1; but on the other side, 2, in front of 4, is omitted. On the right side of the figure is shown the mechanism for the buttons 3 and 4; on the left, for 1 and 2. For movements (3) and (4) the very slightest possible pressure (50 gm. is sufficient) is necessary, in order that the error due to the time con-

med in the movement may be disregarded. For (1) the time taken is inconsequent and a strong pressure makes not only accomplish the purposes already specified stretching springs *c* and *c'*, thus setting the apparatus in movements (3) and (4). Buttons 1 and 2 must, therefore, buttons 3 and 4 merely touched. Before the watch is placed must always be stopped. Fig. 156 corresponds to the momentive been pressed. By pressing 1, the lever *c c c* has been stretched, the left spiral spring has thereby been stretched, and the with *o*, thus leaving the apparatus ready for movement (3) pressed strongly on *m*, thus executing movement (1). After it rises again by the action of the spring directly as shown in the figure, is then pressed, thus executing stretching the right-hand spiral spring. The instrument is measurement of a time interval. By a slight pressure on forward, *c* or *c'* released, the spring recoils, and the lever *d* force and velocity that the loss of time in starting and arrangement neglected. The sensitiveness of the instrument is regulated by change the degree of engagement between *b'* and *c'*.

Two buttons, 3 and 4, are provided rather than one, for hands, not only for technical reasons of construction, but as may be lost in lifting the finger, as would be the case if they were employed for both movements.

ABNORMAL AUSCULTATION SIGNS OVER

Only those abnormal results of auscultation, which is peculiar to auscultation, will be discussed. The rhythm can usually be determined quite as readily as the apex-beat, and will be discussed in the sections on the Apex-beat. The same sections describe the conditions under which the rhythm, as determined by palpation of the apex-beat, differs from that obtained by auscultation. (See p. 152 and the section upon Reduplication of the Apex-beat.)

VARIATIONS IN THE LOUDNESS OR INTENSITY OF

The intensity of the heart tones depends partly upon the position of the heart within and partly upon conditions without the heart. In thin chest-walls, the less distinct the heart tones. In muscular individuals, and particularly in women, the heart tones are apt to be faint, while in men they are generally loud. Edema of the chest-wall lessens the heart tones. Similarly, the heart tones are lessened when the heart is pushed away from the chest-wall, as a result of enlargement of the pericardium, or of precordial emphysema. If the emphysema be extensive, the heart tones are frequently absent. They are intensified, however, if the lung be retracted, as a result of pulmonary contraction or in consequence of a reduction upon the intrathoracic space (kyphoscoliosis, diaphragm, or displacement of the heart).

The heart tones are intensified by a consolidation of the lung about the heart. The factors operating here are the same as those which produce bronchial breathing (see p. 288 et seq.). The heart tones are more perfectly heard, on the one hand, through patent bronchi in a consolidated lung, and, on the other hand, by resonance of the bronchi. Resonance is also responsible for the intensification of the heart tones.

tones in pneumopericardium and in adjoining cavities of the lungs, and also in certain degrees of distention of the stomach with air. In all these conditions the tones acquire a metallic ring.

In other cases, however, the heart tones are intensified or weakened on account of conditions within the heart itself. The intensity depends especially upon the strength of the heart. As a rule, therefore, the tones are louder in strong individuals or when the action of the heart is excited, while they are less audible or even inaudible in weak or very sick individuals, during collapse, and in serious affections of the heart muscle which diminish the capacity for work. Many exceptions to these rules occur in individual cases, because, as we have already seen, the intensity of the heart tones depends upon many other factors besides the mere strength of the heart. The elasticity and smoothness of the valves is one in point, and it may perhaps explain why the heart tones are occasionally very loud in weak individuals with low blood-pressure and in anemic persons. On the other hand, it is possible that a louder tone may be caused by increased rigidity of the valves. (See Increase of the Mitral Tone in Mitral Stenosis, p. 318 et seq.)

If the heart tones be increased, they may be audible not only over the precordia, but also at a greater or less distance from the heart, in the interscapular space, in the head, in the epigastric region, and occasionally even at some distance from the patient's body.

Increase or diminution of individual tones is of greater significance than uniform increase or diminution of all the heart tones. In order to recognize changes in the intensity of individual tones, we must clearly appreciate the relative intensity of the different heart tones under physiologic conditions. The corresponding tones of the right and left heart are generally conceded to be of equal intensity. This is true despite the greater power developed by the left ventricle, because the intensity of the tone depends not so much upon the absolute value of the pressure acting upon the valves, as upon the difference between the pressures acting upon the two sides of the valve at the moment of closure, and the rapidity of the increase in tension. Again, although the mitral and aortic tones of the left heart are naturally louder than the corresponding tones of the right heart, this difference in intensity is neutralized because the aortic and mitral valves are situated at a greater distance from the chest-wall than are the valves of the right heart. Even under normal conditions the corresponding tones of the right and left heart are, however, occasionally of unequal intensity; hence, an increase or diminution of one or the other tone cannot be considered pathologic unless the difference be very marked.

The second aortic tone is increased in hypertrophy of the left ventricle, provided the valves themselves are not seriously diseased and the hypertrophied ventricle is strong enough to produce an increase in blood-pressure. This occurs particularly in arteriosclerosis and in chronic nephritis. The second pulmonic tone is increased similarly in the hypertrophy of the right ventricle which accompanies mitral lesions, or in any other condition obstructing pulmonary circulation (emphysema). Accentuation of the second pulmonic tone is, therefore, an important sign of a compensated mitral lesion. Diminution or weakening of a second pulmonic tone which has been previously accentuated occurs when the compensation in these lesions becomes disturbed as soon as the right ventricle fails to exert sufficient power. But such accent-

uation is also often absent even without such failure as may be easily understood from what has been said consideration of the fact that the grade of valvular lesion is part. Lüthje found that in healthy children of ten to fifteen years of age, the second pulmonic tone is regularly accentuated with the second aortic tone. He attributes this to the influence of the superficial position of the pulmonary artery. [Creighton, working in Cabot's clinic,¹ showed "that in healthy children under ten years of age the pulmonic second sound is louder than the second aortic. In the next decade (from ten to the twentieth year) the pulmonic second sound is louder than the aortic in 66 of the cases. About half of 207 cases between the twentieth and twenty-nine showed an accentuation of the pulmonic second sound, while after the thirtieth year the number of cases showing accentuation became smaller with each decade, until after the fortieth year we found an accentuation of the aortic second in 66 of 100 examined."—Ed.] Under the above conditions, when the heart develops more force, we might expect that the first aortic and pulmonic tones, as well as those over the corresponding aortic and pulmonic valve, would be intensified. Although not usually true, it is occasionally true. As has been mentioned above, the intensity of the first aortic and pulmonic sounds depends less upon the force exerted by the ventricles at the beginning of systole than upon the difference in pressure on the two sides of the closed valve at the time of the increase in tension. Similarly, the intensity of the ventricular tones depends not so much upon the force developed by the heart as upon the degree of systolic pressure and the rapidity of its increase at the valve. Greater working pressure necessarily increase these two factors, provided sufficient time is given the ventricle during diastole and at the same time the heart is under considerable tension.

Here must also be cited the frequently mentioned phenomenon of the systolic tone at the mitral valve in mitral stenosis. That this is partly due to an acoustic deception arising from the accentuation of the tone, which abruptly interrupts the crescendo murmur. (See p. 335.) In other cases the absence of the first tone may be due to the anatomic rigidity of the corresponding rigidity of the mitral valve. The same is true of the tricuspid tone in tricuspid stenosis.

A diminution of individual heart tones is caused by the extensive destruction of the respective valves. Thus, the destruction of the mitral valve causes diminution of the mitral tone; the destruction of the aortic valve causes diminution of the aortic tone. At the same time, we must not forget that many opinions are held about this point. The loss of a portion of the valve does not necessarily cause absence or even marked diminution of the corresponding tone, because the remaining portion can still produce the tones; and, besides, not only the valve but also the surrounding structures, contribute to the production of the tones. For the first tone the walls of the ventricle and the walls of the pulmonary artery, and for the second the walls of the first portion of the pulmonary artery, play an important part.

¹ Loc. cit., p. 176.

If a valve be affected, we shall hear not only the murmur the lesion causes, but also the normal tone. An experienced clinician can frequently detect both the murmur and the heart tone. This is best accomplished by holding the ear at a little distance from the stethoscope, so that the sounds are heard rather faintly. The respective tones may then be diminished by a valvular lesion, but are not necessarily so. It has been frequently stated that the diagnosis of aortic insufficiency depends upon an absence of the second aortic tone. This view is absolutely incorrect. A practised ear can hear the second aortic tone in most cases of aortic insufficiency, although it is often diminished. Absence or marked diminution of the second aortic tone may, however, aid in some cases in the diagnosis of aortic insufficiency.

It is interesting and quite important diagnostically to remember that with a marked insufficiency of the auriculoventricular valve, not only the auriculoventricular tone, but all the tones of that side of the heart, become very much diminished or disappear entirely. The absence of the first tone is not due to the impossibility of producing a first tone in an extensive destruction of the valve, for, as was noted above, the systolic tone originates in all that part of the heart put into a state of tension during systole, including the walls of the ventricle and the arterial openings. For example, a marked mitral insufficiency may show no systolic tone at any point over the left heart, and not merely the first, but also the second, tone over the aortic area may be entirely absent. The cause of this peculiarity is at first glance rather difficult to understand, but it may be explained as follows: On account of the existence of mitral insufficiency, the closure time of the heart disappears. Its place is usurped by a period during which the heart does contract about its contents, but the rapidity of increase of tension is very slow, because the blood in the ventricle immediately escapes into the auricle. Consequently, the mitral valve is never brought into a state of rapid and strong tension, because, as soon as the blood escapes into the auricle, both sides of the valve are subjected to about the same degree of pressure. Hence, the mitral tone is very faint or entirely lacking on account of the absence of a closure period. A further result of the regurgitation at the beginning of systole is that the walls of the ventricles, the conus arteriosus, and the closed aortic valves are not sufficiently nor suddenly enough stretched to produce a strong systolic tone. Consequently, either no systolic intracardial tension tone or only a rudimentary one originates over the ventricle and over the beginning of the aorta. In addition, a marked mitral regurgitation may also cause diminution or absence of the second aortic tone, because the blood regurgitated into the auricle by the ventricular pressure rushes back again into the ventricle at the beginning of diastole, thus reducing below the normal the difference in pressure upon the two sides of the valves, and their tension. Other things being equal, the same reasoning applies to the right heart and to tricuspid insufficiency. All the heart tones may be diminished or entirely absent in a combined mitral and tricuspid insufficiency. The absence of the heart tones in insufficiency of the auriculoventricular valves is of double diagnostic significance. In the first place, it aids in determining the degree of insufficiency. Mitral insufficiency with no tone over the left heart must necessarily be a serious lesion. This law applies only during the period of compensation. During disturbance of compensation the heart tones may be enfeebled

on account of diminished systolic force. On the absence of heart tones may occasionally prove the aortic insufficiency which could not otherwise account of the absence of a mitral murmur. If, compensated mitral stenosis be diagnosed, and if heart tones are absent on the left side, the stenosis is proven an insufficiency of the mitral valve.

Finally, in regard to the audibility of heart tones accompanied by murmurs (see p. 327), it is to be remembered so frequently made, that the tones are masked based on an erroneous conception. The same conditions of the functions of the valves and produces the murmur prevent the production of a tone or diminish its force; however, be masked by the murmur. Provided that its sound, like a sharp blow in the midst of the slow murmur, can always be detected by an expert especially if he employ the device of holding the ear from the stethoscope. (See p. 318.)

In the graphic representations of the results the author has expressed the intensity of the heart tones of the metric signs and accents used to represent example, Fig. 173, the diagram of mitral insufficiency and second pulmonic tone.)

ALTERATIONS IN THE TIMBRE OF THE HEART TONE

The timbre or quality of the heart tone may vary under various conditions. Whether the normal heart tones are similar to musical tones depends upon a number of factors, especially upon the elasticity of the walls of the larger vessels. However, a drum-like sound is rather rare in healthy individuals. Occasionally in healthy individuals, are not clear; they are not a sharp blow, but produce a rough, irregular sound. The purity in the tones of a normal heart has not been observed but apparently indistinct reduplication of the tone is due to rudimentary murmurs which occur even in the healthiest chief factors.

Marked variation in the timbre of the heart tone occurs in various pathologic conditions. Thus, in arteriosclerosis the sound is not only accentuated, but possesses a peculiar ringing character, as has been mentioned upon pp. 316 and 317. In the presence of air contained in cavities, the heart tone is intensified, but assumes a peculiar metallic character.

The tone called "*cliquetis metallique*" is a metallic tone heard over the ventricles when the heart is enlarged, not only in healthy individuals, but also in heart disease, nervous palpitation, and in every form of cardiac enlargement. Occasionally it can be heard at some little distance, as in the case of the violent vibration transmitted to the chest-wall and stomach, in consequence of the accelerated cardiac action.

Impurity or roughness of the heart sound is observed in many persons, but it is more commonly due to some disease of the heart. It is frequently due to slight changes in the valve which

disturb its function, merely affecting its uniform tension (roughness or rigidity of the curtains, pathologic deposits on the valve cusps), but in some cases it is the result of a valvular lesion which is not sufficiently pronounced to produce the characteristic murmur. Under such circumstances an impure tone might be regarded as a rudimentary murmur; because, if the cardiac action be accelerated, *e. g.*, by directing the patient to get up and to sit down again several times in succession, the impure tone is frequently replaced by a true murmur. Autopsy findings occasionally suggest that the impurity of the systolic tone is due to changes in the muscle sound, the result of structural changes in the heart muscle (fibrosis).

APPARENT OR ACTUAL REDUPLICATION OF THE HEART TONES

Normally, only two tones are heard over every point of the heart, a systolic and a diastolic tone; but under both physiologic and pathologic conditions three or even four tones may be distinguished. This peculiarity may depend upon either one of two causes: either there is only an apparent reduplication, *i. e.*, under normal conditions all systolic tones and all diastolic tones occur at the same moment, but in any given case such a coincidence may be disturbed, or else there may be an actual reduplication of the sounds, due to the production of abnormal tones.

Division, Splitting, and Reduplication of Heart Sounds ($\frac{2}{3}$ time).—When two tones with a very short interval between them are heard in place of one heart tone, the tone is said to be split or reduplicated. If the two tones occur very close together, we speak of a *division* or *splitting* of that heart tone, while we limit the term *reduplication* to those cases where the two tones are separated by a longer interval. The three tones do not follow each other in $\frac{2}{3}$ time, but the heart rhythm preserves the normal $\frac{2}{3}$ time. Reduplication of the first sound gives an anapest, $\sim \sim -$ (lubb-lubb-dúpp); reduplication of the second sound, a dactyl, $- \sim \sim$ (lúbb-dupp-dupp).¹ The double tones in splitting, which is only indistinctly separated from reduplication, are repeated so rapidly that the examiner obtains the impression of a single tone accented at the beginning or at the end. This is commonly expressed by combining the metric signs $\sim \sim$ and $\sim \sim$.

This splitting or reduplication may be caused—(a) by an imperfect coincidence of the normally synchronous tones of the right and left heart, or (b) by the production of abnormal tones.

(a) Splitting and Reduplication as a Result of Imperfect Coincidence of the Normally Confluent Heart Tones.—It is not surprising that various conditions should disturb the coincidence of the heart tones, considering the great number of factors influencing the course of the heart's action (nervous influences, variations in pressure in the different parts of the heart chambers and in the rest of the circulation). It is, on the contrary, more remarkable that any such coincidence of all systolic and all diastolic phenomena should occur at all; and suggests a very perfect balance of the cardiac mechanism.

¹ The normal accentuation of the systolic tone over the auriculoventricular valves and of the diastolic tone over the great vessels is effaced by the splitting of the tones. Hence, reduplication and splitting of the first tone produces an anapestic rhythm, not only over the great vessels, but also over the auriculoventricular valves. In the same way splitting of the second tone produces a dactyl, not only over the auriculoventricular valves, but also over the great vessels.

In cases in which this coincidence is lacking, the location may be heard best half way between the areas of the left and the right heart.

Faulty coincidence, producing a reduplication first tone, is occasionally caused by a failure of the tract at the same moment; under such circumstance tone must be audible over the entire heart.

In many other cases the reduplication or splitting which is heard only over the great vessels, might consist of the normal first tone, which is increased by closed semilunar valves, plus a second part of the tone during the expulsion time by the pulse-wave in the artery. As a matter of fact, there is no reason why which can produce a tone in the carotid artery should not produce a tone in the aorta. Such a splitting of tone does not occur because the closure time is so short that the tone that of the expulsion time are merged into one. The reduplication or splitting of the first tone, as heard over the great vessels, would depend upon a prolongation of the closure time, thus possessing some clinical significance. This explains the physiologic reduplication of the first tone, heard over the great vessels, particularly during those phases of respiration when the pressure is elevated (according to p. 135); that is, during expiration, with rapid respiration during expiration.

In a recent article,¹ R. Geigel maintains that the splitting of the first tone, depending upon an expulsion tone in the arteries, audible apart from the intracardial tension, can be heard under normal conditions if one listens to the carotid artery, instead of confining one's self to the classic location over the great vessels. As the author has already pointed out, there is no doubt that the blood, streaming into the aorta, produces a tone in it as in the carotid. Moreover, there is very little reason why this tone to be appreciated by the ear as separate from the tension tone, since the closure time is about 0.07 second. Helmholtz (cited by R. Geigel), the ear can appreciate tones 0.01 second apart. R. Geigel attributes the neglect of this splitting to its lack of diagnostic applicability. For its demonstration, according to Geigel, listen from the apex toward the base; the intermediate territory will always be found where the splitting is heard. From this spot the first tone becomes the normal first tone, and finally the only one—toward the apex; the second tone remains. It is seldom a question of a distinct reduplication, but of a splitting or even only of an impure first tone.

Faulty coincidence, producing a splitting of the first tone, is frequently observed in healthy individuals in the course of inspiration and in mitral lesions—both aortic and pulmonary stenosis. A common explanation of the splitting of the first tone is that the aortic and pulmonary semilunar valves do not close at the same instant. This lack of coincidence, under the conditions mentioned, is supposed to be due to an abnormal difference in the pressure between the aorta and pulmonary artery. High pressure closes the valves sooner than low pressure. The second part

¹ Münch. med. Woch., 1906, No. 17.

is certainly incorrect, because even under physiologic conditions the pressure in the aorta differs enormously from that in the pulmonary artery, and because, furthermore, Ceradini has demonstrated that the closure of the semilunar valves occurs instantly and independently of the degree of pressure in the artery as soon as blood ceases to flow out of the heart. The second tone is not caused by the closure, but by the sudden tension of the closed semilunar valves, and takes place at the moment when, after a period of rest, the ventricular diastole begins. So far as any lack of coincidence of the left and right tones is concerned, splitting or reduplication of the second tone might be referred to lack of coincidence in the beginning of diastole, but such an assumption is quite unnecessary. The following explanation is more plausible: The semilunar valves, which are closed at the end of systole as a result of the marked diastolic drop in pressure within the ventricles, are suddenly forced back and made tense against the ventricle by the pressure in the aorta and pulmonary artery at the beginning of systole. This produces the diastolic tone. Any factor which tends to prevent a rapid diastolic drop in pressure within the ventricles will probably delay the corresponding second tones, while any factor which favors a drop in pressure will hasten it. As a matter of fact, such factors are present under those conditions where reduplication or splitting of the second sound exists.

Inspiration in a healthy individual, with moderately rapid respiration (see p. 134), detains the blood in the dilated pulmonary vessels, and so delays the filling of the left ventricle. As a consequence, the difference in pressure between the aorta and the left ventricle is rapidly increased, producing sudden diastolic tension of the aortic valves, and thus causing the second aortic tone to occur before the second pulmonic, as evidenced by reduplication or splitting of the second tone. The conditions are similar in mitral stenosis, where the flow of blood into the left ventricle is obstructed by the narrowed valve; consequently, the aortic valve is put under tension sooner than the pulmonic. In mitral insufficiency, on the contrary, the left ventricle is filled very rapidly during diastole, on account of the congestion in the auricle; consequently the aortic valve is put under tension somewhat later and the second aortic tone is delayed. If this explanation be correct, the second aortic tone is hastened during inspiration of a healthy individual, as well as in mitral stenosis, but delayed in cases of mitral insufficiency. This is actually the fact, because in mitral stenosis and in healthy individuals the second part of the double tone can be perceived in the left intercostal space as a loud second pulmonic tone, while in mitral insufficiency in the same place, the first part of the double tone is more distinctly heard.¹

Reduplication of the second tone so frequently accompanies mitral lesions that it should be considered as of some diagnostic significance, provided that it can be proved to be independent of any definite phase in breathing.

(b) Splitting and Reduplication as a Result of the Production of New Tones.—In some cases the reduplication of tones is due not to

¹[To prove that this explanation is correct, we should determine whether the inspiratory can be changed to an expiratory reduplication in healthy individuals breathing very slowly; because slow respiration produces exactly an opposite effect upon the ventricular filling from rapid respiration.—Ed.]

failure of coincidence of the normal tones, but to abnormal tones. The splitting and reduplication distinctly at a particular valve area, not midway. rhythm is an exception, being often heard over p. 325.)

Splitting or reduplication of the first tone over valves may occur where mechanical conditions, differences in size of the individual valve segments, put under tension at exactly the same moment separate systolic tones.

This explanation would even account for the tone at the tricuspid valve.

In certain cases the *reduplication* or *splitting* due to the production of new tones and not incidence. Circumstances are conceivable where variations (dicotism) due to elasticity or reflected pulse may cause a supernumerary second tone diastolic mitral tone may produce the rhythm of a triple rhythm. (See p. 325.)

Triple Rhythm ($\frac{3}{4}$ Measure).—1. *The tri-*
tones in mitral stenosis consists of three approxi-
either exclusively or most plainly at the apex ar
There is no such grouping of two of the three to
reduplication (splitting or doubling), but the hea
normally, in $\frac{3}{4}$, beats in $\frac{3}{4}$, time. The accent of
second of the three tones.' With this rhythm
mitral stenosis (see p. 334) may or may not be
it may be brought out by simply accelerating
we then find that a presystolic murmur usurps
the three tones, thus proving that the latter is a
tone. The second is the normal systolic tone,
apex-beat; and the third is consequently the dia-
stolic tone. The first stroke of the
auscultation area of the mitral valve is another
from this valve. It is, therefore, an abnormal
thickened cusps of the mitral valve remain to
diastole, and so the auricular contraction plu-
produces the tone. The adherent mitral val-
a diaphragm between the auricle and the ventric-
just as the systolic vibration of this diaphrag-
tone, so does a presystolic (diastolic) tension f-
traction occasion a new presystolic tone. This
readily appreciated in typical cases by the pres-
first tone; and it is of diagnostic importance
mitral stenosis not accompanied by a presystolic
One should, however, be careful not to confu-
another very common peculiarity of mitral lesi-
of the second tone, due to the imperfect coincide-
and second pulmonic. The rhythm in this case
the localization over the mitral valve is especial
presystolic tone. (See p. 321.)

¹At the mitral area } ∪ ∪ ∪ ∪ ∪ ∪ { to
 at the apex.

It must, however, be stated that the diastolic mitral valve tone of mitral stenosis is not always presystolic, for it may appear at another period of diastole, in case tension of the mitral valve occurs not only during the presystolic contraction of the auricle, but also at any earlier period of diastole, from the recoil of the blood at the adherent mitral valve. In such cases exactly the same rhythm results as in reduplication of the second tone (p. 321 et seq.); and the significance then can be determined only by its appearance over the mitral valve, as contrasted with its ordinary appearance over the base or at the apex.

2. *Gallop rhythm* is a triple rhythm, heard, for the most part, over the entire heart; the tones follow at approximately equal intervals, and the second ordinarily is accentuated at the apex and the third at the great vessels; thus:

Apex :   tatáta tatáta
Great vessels :   tatatá tatatá

This rhythm means that an extra tone occurs during diastole, i. e., before the normal first tone. We can ordinarily distinguish it from the presystolic tone of mitral stenosis, because it is generally to be heard with nearly equal distinctness all over the heart.

Its explanation is not yet quite certain. We have no physiologic grounds for supposing that the contraction of the ventricle takes place in two steps. Potain¹ formerly held that the auricular contraction made the ventricular wall tense and so produced the first of the three tones; and Kriege and Schmall's² cardiographic representations supported his theory. Potain, however, later³ modified his explanation, to the effect that the extra tone which occurs during diastole, or before systole, is not due entirely to the contraction of the auricle making the heart-walls tense, but also to a sudden, abnormal passive tension of the ventricular wall during diastole, which tension is occasioned, in the first place, by the *vis à tergo* of the entering blood, and, in the second place, by the auricular contraction. The extra tone frequently coincides with presystole; but sometimes it approaches more nearly the preceding diastolic tone than the following systolic tone, and so makes the rhythm quite different. In addition to the normal systolic shock we can frequently feel or see a diastolic or presystolic shock of the anterior heart-wall, coinciding with the extra tone, so that the above explanation seems quite probable.

Such an explanation makes *gallop rhythm* the expression of an abnormally stimulated heart activity, which produces either an abnormally quick diastolic relaxation and a consecutive sudden passive tension of the ventricular wall from the entering blood, or an increased contraction of the auricle.⁴ Conditions which apparently are directly opposed, produce a gallop rhythm, viz., *cardiac insufficiency*, which is always connected with an irritability of the heart; and the *stimulated*

¹ Union med., November 11 and 18, 1876; January 6 and 27; February 29, March 11, 1875.

² Zeit. f. klin. Med., vol. xviii, 1891, parts 3 and 4. ³ Sem. méd., 1900, p. 22.

⁴ Stefani's experiments concerning the effects of digitalis on diastole in artificial pericardial effusion give some support to the view that diastole of the ventricle is an active process. In that case a stronger ventricular diastole may be the cause of gallop rhythm. Brauer (Cong. f. inn. Med., 1904) inclines toward this view, especially since his graphic demonstration of the force of his so-called "thoracic rebound." Sherrington has shown that relaxation of the external rectus muscle of the eye may protrude the eyeball, which is the direct opposite of its contraction, so that assuming an active ventricular diastole is not so unreasonable as might appear at first sight.

cardiac action of health, of exophthalmic goiter, and of nephritis with high tension pulse. Potain distinguished between a gallop of the right and of the left heart, according to whether the rhythm is heard more plainly over the right or the left side.

Gallop rhythm, then, is a diastolic phenomenon. "*gallop rhythm*" is better called a doubling of the first tone, as it is heard over the great arteries, and is due to a prolongation of the closure time.

PENDULUM OR FETAL RHYTHM OF THE HEART (Embryocardia)

By this is understood a rhythm in which the systolic and diastolic equal those between the diastolic tones, i. e., the short and the long pauses are equal. This rhythm has been principally observed with increased pressure in the arterial system (*nephritis*). Pawinski's¹ experiment shows that it depends upon a prolongation of the systole, a prolongation of the closure time, which, in turn, is due to the increase of pressure the ventricle has to overcome before it can open the aorta.

Huchard designated as *embryocardia* a characteristic rhythm observed in severe infectious conditions and in the terminal stage of disease. On account of the great rapidity of cardiac action both pauses have the same duration and both tones the same resonating character. It should therefore be defined as tachycardia plus pendulum rhythm. The same phenomenon some time ago under the name of fetal rhythm has been explained. Its explanation is still unknown.

HEART MURMURS

These are variable sounds heard either in addition to the heart tones, sometimes usurping their place. They are nearly always associated with a diseased condition, but they are occasionally heard in health.

An exact distinction between *tone* and *murmur* is difficult. Acoustically, the heart tones depend as much as the murmurs upon non-periodic sound vibrations, so that it is not correct to say that tones consist of regular, and murmurs of irregular vibrations. An approximate periodicity or regularity of the vibrations is characteristic of tones, and thereby an approach to a definite pitch is attained, more applicable to murmurs than to tones, e. g., the murmur of aortic regurgitation is best described as musical. For practical diagnosis the distinction between *tone* and *murmur* depends chiefly upon the duration of the sound. The *tone* arises from a single sudden disturbance of equilibrium of a sound-producing body; the *murmurs*, on the contrary, from repeated disturbances of equilibrium. Any evidence of a *tone* must depend upon continued vibrations of the body, and inertia; in the *murmur*, on the contrary, upon repeated vibrations due to new applications of the moving force. Compared to the sound produced by striking once upon a drum, the *murmur*, to the sound produced as long as one blows into a reed. Acoustically, they are noises in either case, though they may approach less nearly to a musical tone or resonance. Tones are distinguished from murmurs essentially by their brevity and rapid, almost instantaneous, dissonance. What has been said of the heart tones applies to the heart murmurs.

¹ Deut. med. Woch., 1891, No. 4.

above in regard to murmurs and tones of the heart is quite as true in regard to those of the vessels. (See p. 347.)

Some of the murmurs heard over the heart originate from within, some from without; the former are called *endocardial*, the latter, *paracardial*.

Endocardial Murmurs

These are of two kinds: *valvular murmurs*, depending upon a disturbance of the cardiac valves, and *accidental murmurs*, having no connection with a disturbed valve function.

Endocardial murmurs are more or less prolonged noises (thus contrasting with the heart tones, which are brief and sound sharply cut). They are very diverse in character, generally blowing or puffing, sometimes scraping, musical, even singing or whistling. The heart tones are expressed symbolically by the metric signs and $\underline{\quad}$ \smile and the endocardial murmurs by the crescendo and diminuendo signs $<$ and $>$. Two elementary forms of murmurs may be differentiated:

1. $>$ Diminuendo murmurs, which begin sharply and gradually fade away.

2. $<$ Crescendo murmurs, which begin gradually and end sharply. Two combined forms may be derived, thus:

3. \diamond Murmurs which begin, and fade away, gradually.

4. \times Murmurs which begin and end sharply, and which in the middle are of minimum intensity.

In most cases the *endocardial murmurs* are audible only to auscultation; but exceptionally they may be heard at a distance, or even appreciated by the patient himself. These so-called distance murmurs have generally a musical, singing, or whistling character.

We are indebted to the experiments and researches of Corrigan, Kiwisch, Heynsius, Thomas, Weber, Chauveau, Marey, Thann, Nolet, and others¹ for the physical explanation of the peculiarities of endocardial murmurs such as those mentioned above. Normally, the blood flows through the heart chambers without noise, so that a murmur must be attributed to some abnormality of the blood-current in the heart, as the following experiment illustrates:

If we have a glass tube ($a-b$ in Fig. 158, I) through which a stream of water is flowing, no murmur can be heard at the point c so long as the current is moderate. If, now, the rapidity of the current be increased by supplying more water, a continuous blowing sound can be appreciated at c , which simulates to a certain extent an endocardial murmur. Such a simple experiment explains the *first essential* for the origin of endocardial murmurs, namely, *the rapidity of the current*, which, other conditions remaining the same, naturally depends upon the hydraulic pressure causing the stream.

By narrowing or widening the caliber of the tube at a certain place (c in Fig. 158, II, III, and IV) we possess another means of producing a murmur in the silent current, always provided the rapidity of the stream is sufficient. If in such a tube the murmur be not heard, it may be produced, or if very faint, it may be intensified by increasing the rapidity of the flow, although the same rapidity in the straight tube

¹ An excellent historic presentation of our knowledge of heart murmurs is found in Rosenstein's section on Heart Diseases, in Ziemssen's *Handbuch der spec. Pathol. u. Therapie*, vol. vi.

would furnish no sound. This, then, explains the formation of endocardial murmurs, viz., *alterati blood-channel*.

In order to clear up these fundamental principles let us refer to Fig. 158, III, that the fluid flows from a narrower into a wider tube. Experimental physics teaches us that under such circumstances a certain suction power upon its surroundings. This, to a certain extent narrows the widened portion of the more distant tube; the difference in the lumen is lessened; the suction ceases; the bulge again, and the process is repeated over and over again as the current flows. Thus the current occasions lateral vibrations of the tube-wall; and, secondarily, of the narrower part, and of the widened part and follow the same rhythm. These murmurs arise from these vibrations of the tube-wall, transmitted just as well against as with the stream. If the current is reversed, as in Fig. 158, II, the result is the same. And even if a widened tube is suddenly and permanently narrowed, the vibrations of the wall are exactly the same, whether the current is in

Fig. 158.—The origin of current murmurs: a, b, Current of

or of the upper arrow. In the former, suction takes place as the fluid streams from the wide into the narrow tube, and the vibration occasioned by the narrowing is like that of the suction in I, so that a sufficiently rapid current will produce murmurs of the same caliber, as in I. For friction is always to be found in the tube, and so the layers quiescent against the wall rubbed upon by the current layers, act like an infinite number of microscopes. It is proved in these experiments that the murmurs over the narrow part always appear stronger than over the wide. And this we remember that, according to Pascal's law (the law of transmission of vibrations in the wall causing the sound increase in proportion to the contact surface between fluid and wall. This is of great importance in the relations of transmission of the cardiac murmur experimentally only upon rubber tubes, since stiff tubes (like glass) transmit the sound too perfectly and too far.

The following experimental facts, adduced by Weber, are of great interest to be mentioned:

1. Murmurs arise more readily if the walls of the tube are thick.
2. If the inner surface of the tube be roughened, murmurs arise more readily, requiring a less rapid current.

3. A much greater rapidity of current is necessary to give rise to murmurs in glass or brass than in yielding or distensible tubes (rubber tubes, intestines, veins).

4. Quicksilver causes murmurs more readily than water, water more readily than milk, milk more readily than blood mixed with water, heavy fluids more readily than light fluids, thin fluids more readily than tenacious fluids.

5. Sometimes the vibrations of the tube become so strong that they can be appreciated not only by the ear, but also by the sense of touch. They feel like sand running over the finger.

6. With a certain grade of rapidity of the current and narrowing of the tube a finer, more singing tone (musical murmur) can sometimes be heard.

7. Increased or diminished tension of the wall (by means of increased pressure of the fluid) has little influence upon the murmur so long as the rapidity remains the same.

8. If we gradually narrow a tube through which fluid is running, a murmur will appear after a certain degree of this compression. Increasing the compression will increase the intensity of the murmur up to a maximum, then diminish it, and finally cause it to disappear.

The diagrams make it plain that under the conditions which occasion current murmurs, eddies arise at the point in question. These can be plainly demonstrated by using a glass tube and suspending a light, insoluble powder (lycopodium) in the flowing liquid. It has been supposed that these eddies were the causes of the current murmur.¹ Such a supposition is, however, but partially correct, because the only parts which produce actual sound must be in permanent vibration, and fluids remain in permanent vibration only with difficulty; while in such irregular cavities as those of the heart and vessels such permanent vibrations would be hardly conceivable. In any case eddies in themselves have nothing in common with permanent vibrations. The fluid shares in the vibrations of the wall, but the common vibration of the two is due to the wall, not to the fluid. It is, however, clear that the eddies are an integral part of the entire process; and probably they are essential to the origin of permanent vibrations of the tube-wall. They must exist together. Thomas Weber has aptly compared the part of the fluid and the eddies to the rôle of the moving violin bow; the part of the vessel-wall vibrations to the rôle of the sounding string.

Valvular Murmurs.—Valvular Murmurs in General; Organic and Functional Valvular Murmurs.—To explain the elementary relations of valvular murmurs it is better, for the moment, to neglect the part played by the rapidity of the current.

Valvular murmurs may arise at any valve when the blood-current, either during systole or diastole, flows into an adjoining chamber through a narrow orifice. Such a result may happen in one of two different ways: either the valves do not open completely, forming a *stenosis*, or they do not close completely, and so allow a blood-stream flowing in an abnormal direction to escape through a narrowed opening, thus forming an *insufficiency* or *regurgitation*.

Anatomically, a *stenosis* is caused by adhesion of the individual segments of the semilunar or of the auriculoventricular valves, or else by a shrinkage of the orifice. *Insufficiency* of the valves arises from the shrinkage of the curtains in the long axis, from partial destruction or perforation of the valves, from tearing free of the entire curtain, or from uneven new deposits [vegetations.—Ed.], which mechanically prevent a perfect closure of the valves. In any of these cases we speak of an *organic* or *anatomic valvular lesion*.

Without being anatomically diseased, a valve may, however, be incapable of closing if the orifice at which it is inserted becomes dilated. This is called a *relative insufficiency*. The curtains no longer suffice to close the widened orifice, or the position of the papillary muscles is so distorted by the ventricular dilatation that the valves can no longer perfectly close. Widening of the orifice in relative insufficiency of the

¹ Heynsius is the chief advocate of this theory.

semilunar valves (i. e., dilatation of the walls of the pulmonary artery) depends upon increased blood-pressure, elasticity of their walls (arteriosclerosis), or upon pathologic elements in them (inflammatory swelling). The relative insufficiency of the auriculoventricular valves is in part dependent upon a diastolic distention of the ventricle by a great influx of blood from the veins, or, with increased force, an incomplete emptying of the ventricle. If these insufficiencies be not permanent, but depend upon some temporary derangement of function (transitory dilatation), they are called *relative insufficiencies*.

In contrast to the purely mechanical insufficiency (relative insufficiency in the narrower sense) is "valvular insufficiency" (Friedreich) when there is no mechanical defect. This is due to a lack of proper functioning of the valve which prevents the normal closing of the valve. It may result from muscular weakness (disturbances of compensation) or, however, it is usually combined with dilatation of the heart. Disturbances of innervation, e. g., in chorea.

The blood-current producing the murmur in aortic insufficiency is directed normally; in an insufficiency, abnormally. So, without further explanation, it is apparent that a murmur is heard during that phase of cardiac action in which the valve is opened; an *insufficiency murmur*, on the contrary, which the valves should shut.

Compare here the following scheme:

	Systolic murmurs
Insufficiencies.....	{ of mitral, of tricuspid,
Stenoses.....	{ of aorta, of pulmonar,

Valvular lesions are, as a rule, accompanied by other rarely decided lesions, which perhaps were only suggested by some other clinical conditions, are found post mortem that never gave a murmur. This is easily understood, that a definite minimum of current rapidity for each lesion is essential to cause a murmur, and also that the nature of the murmur is too pronounced (p. 328). Mitral stenosis, e. g., no murmur, because the diastolic current is relatively weak, as diastole lasts much longer than systole. For the diagnosis of a lesion must be considered as a possibility in every case, whether associated with a murmur or not.

Significance of the Timbre (Quality of the Murmur) and Loudness (Intensity) of the Valvular Murmur.—It is inclined to overvalue the diagnostic significance of the endocardial murmur and to draw conclusions from the timbre of the altered valves. It has, however, been shown that conclusions based upon the rough, blowing, musical, or whistling character of the murmur are entirely untrustworthy, as they vary so much with the accidental configuration of the heart that we deem it of very little importance. Neither the blowing or scratching character of a heart murmur certainly indicates its being of accidental nature. (See p. 340 et seq.)

Even the *loudness of the murmur* does not necessarily correspond to the degree of a valvular lesion, as some physicians are still inclined to believe, for, as the experiments with the tubes prove (see p. 329, Law 8), a certain rapidity of current is requisite to bring out a maximum murmur through a definite narrowing. If the narrowing of the tube be too slight, the murmur is weak; if the narrowing be too pronounced, the murmur is, under some circumstances, still weaker, probably on account of the great loss of energy. In every valvular lesion, whether insufficiency or stenosis, as the defect increases the murmurs increase in intensity until a maximum is attained; then, despite further increase in the valvular defect, the murmur diminishes again. Now, it is not possible, in a given case, to determine from the character of the murmur whether the valve lesion (*i. e.*, the narrowed channel) has already passed or has not yet reached its acoustic maximum, so here, again, no sure inference can be drawn from the loudness of the murmur. Much more trustworthy conclusions are to be deduced from carefully heeding the various cardiac functions and from other methods of examination, particularly the estimation of the size of the heart.

How little the loudness of the murmur shows the severity of a valvular lesion is proved by the clinical fact that cardiac invalids with exceptionally loud murmurs may live for years, whereas others, with scarcely audible or even no murmurs, may very soon succumb to their malady.

Murmurs vary a great deal in the same patient, depending upon the kind of cardiac activity. Even a very brief medical experience teaches that the patient's condition is by no means always the best when the murmur is scarcely audible, but frequently the worst. The first essential for murmurs mentioned in our theoretic discussion, *viz.*, current rapidity, easily explains this seeming inconsistency. If the patient's condition be good, a vigorous current is flowing through the diseased valve and the murmur is, therefore, strong and loud. If by weakening of the cardiac power the patient's condition be impaired, the current which causes the murmur is diminished, the murmur weakens, and finally even disappears. This sometimes makes the diagnosis of valvular lesions very difficult, especially because we generally examine patients when things are not going well with them. We must, therefore, often withhold our opinion until our treatment has improved the patient's condition sufficiently to bring out the murmurs; or we may temporarily increase the current rapidity and so bring out a suspected murmur by causing the patient¹ to execute some active movements augmenting the heart action.

A very loud murmur is only rarely accidental; so that although the loudness of a murmur is not necessarily a measure of its severity (p. 340 et seq.), still it is an argument against its accidental nature.

The influences external to the heart which modify the loudness of the valvular murmurs are the same as those affecting the heart tones. (See p. 316.)

We should always auscultate a patient in different positions, particularly standing and lying down. This is especially important in the determination of murmurs, because position has a great influence upon their character and intensity. Frequently a certain murmur can be heard only in the recumbent, another only in the erect, posture. This

¹ Up to a certain grade this is also possible in insufficiency.

cannot always be satisfactorily explained by the current and the blood-pressure are decidedly different. We will refer under the individual valvular relations which apply to this point.

The Localization of Valvular Murmurs.—The essential requisite for an exact localization consists in localizing the murmur, *i. e.*, the valve it arises from. This is not always easy, because not only where they arise, but by transmission the same rules apply to the localization of murmurs of tones (p. 309 et seq.), *i. e.*, murmurs heard at the apex; of the tricuspid, at the lower end of the pulmonary, in the second intercostal space to the right of the sternum; and of the aortic valve, in the second right intercostal space to the left of the sternum.

Exceptions to these rules are so numerous that a special chapter seems necessary. If the heart chambers at either side be of unequal size, a stronger (louder) murmur arises over the smaller chamber. (See Weber's experiments.) Murmurs originate at some distance from the heart and are heard more plainly at a spot upon the thorax than at the point of projection of its place of origin. This is called *transmission* through the medium of the thorax, with or against the current. If transmitted with the stream, the murmur is louder than if transmitted against it, just as "the wind carries the sound."

1. *Systolic murmurs arising at the aortic valve.*—The loudest at the aortic area (the second right intercostal space, where the aorta lies near the thorax-wall, and the current causing the murmur is directed to that point). If transmitted, however, strongly upward to the carotid, it may be utilized in doubtful cases in order to distinguish between aortic insufficiency and aortic stenosis. Not infrequently murmurs are heard plainly over the left ventricle at the apex. This is simple enough to understand, because the current flows from the left ventricle (p. 327).

2. Ordinarily, the *diastolic murmur of aortic insufficiency* is heard so plainly at the aortic area as it is further from the heart. Perhaps most frequently it is loudest at the middle of the sternum. The reasons are: first, that the murmurs are situated deeply, at a distance from the aortic area; second, that the murmur arises principally during diastole (p. 329); and third, that the current causing the murmur flows from the aorta to this chamber. The murmur is also frequently to be heard over the neck vessel.

3. The *systolic murmur of mitral insufficiency* is ordinarily heard best at the apex, and not over the mitral valve. Despite the location of the valve and the fact that the murmur flows through the blood-current, which is in the upper part of the left ventricle is so complete that the murmur is heard in the ventricle and lung that the murmur is heard in the chest. Another reason is that, at the beginning of systole, the current is much larger than the auricle, and so a louder :

ventricle (*i. e.*, apex) than over the auricle. There are instances, however, where the systolic mitral murmur is best heard at the base of the heart, in the vicinity of the left auricle, at the projection spot of the mitral valve, in the third intercostal space, to the left of the sternum. Probably this occurs chiefly when there is a marked dilatation of the left auricle. The lung is then pushed aside and the left auricle exposed, which naturally facilitates the appreciation of the murmur over it and the mitral valve. Besides, the current causing the murmur is directed to the region of the left auricle. Marked dilatation of the left ventricle also pushes the maximum point of the systolic murmur from the heart apex upward, because such a dilated left ventricle crowds the right ventricle and the lung and applies itself more completely to the thorax, so that the region of the mitral valve and the left auricle is exposed.

4. In *mitral stenosis* the direction of the current causing the murmur is an especial reason for the sharp localization of the diastolic murmur of this valve lesion (even more than the mitral tone, see p. 309) at the apex. If faint, the diastolic murmur of mitral stenosis can sometimes be heard only just outside the apex. This is especially applicable to the so-called presystolic murmur (see p. 335), in which case there is also another reason, *viz.*: the left auricle during presystole is small and the left ventricle large. But a pure diastolic mitral murmur (p. 335) is frequently heard best over the auricle, because it arises at the beginning of diastole, when the left auricle is wide, and the left ventricle, in comparison, is then narrower.

5. The *systolic murmur of tricuspid insufficiency*, in spite of the direction of the current upward, is heard most distinctly at the tricuspid area, the lower end of the sternum or somewhat to the right of it, because here the right ventricle as well as the right auricle lies near the thoracic wall (Fig. 120). Other systolic murmurs, excepting perhaps the systolic murmur of the rare pulmonary stenosis, are not plainly transmitted to this spot.

6. The *diastolic murmur of tricuspid stenosis*, a rare lesion, has its maximum intensity at the tricuspid area, the lower end of the sternum, because the current from the affected valve above is directed toward this spot, and because both cavities, right auricle and right ventricle, here lie close to the thoracic wall.

7. The *systolic murmur of pulmonary stenosis* is auscultated at the pulmonic area (the second left intercostal space) and over the right ventricle.

The murmur of pulmonary stenosis is frequently heard over the greater part of the anterior surface of the heart, because the right ventricle is ordinarily so dilated in this lesion that it occupies most of this area; and because (p. 329) the murmur arises not only at the stenotic valve, but also over the right ventricle. This is a point which should be carefully heeded to prevent confusion in diagnosis.

The pulmonary stenotic murmur should be plainly transmitted into the interior of the lung; it should also be heard very distinctly beneath the left clavicle (where aortic murmurs are only faintly transmitted), or behind, between the shoulder-blades, and, in contrast to the murmur of aortic stenosis, it is either not transmitted at all, or only very slightly, into the neck vessels.

8. The *diastolic murmur of pulmonary insufficiency* is auscultated at the pulmonic area. Like the murmur of aortic insufficiency, it can,

circulatory disturbances, as well as many other symptoms. A differentiation is thus possible in almost all cases.

Most murmurs are represented by the diminuendo sign, because their intensity is greatest at the beginning of the phase of cardiac action to which they belong. The reason is that the blood-current is then most rapid. The diastolic murmurs of the auriculoventricular stenoses are the only exceptions, because the auricular contraction increases the current rapidity and they are represented by the crescendo sign.

It should be noted that an actually uniform crescendo may occur during the progressive contraction of the auricle and the concomitant dilatation of the ventricle. The murmur really increases during the course of the auricular systole on account of the increasing difference between the sectional area of the contracted auriculoventricular orifice and that of the ventricle. (See Weber's Laws of Origin of Murmurs, p. 328.)

Tricuspid stenosis is so rare as to be practically neglected, so that a *presystolic accentuation at the end of the murmur* is practically pathognomonic of mitral stenosis. In puzzling cases this very characteristic accentuation at the end of the murmur sometimes aids in distinguishing the phases of cardiac action. Although theoretically it is not a uniformly regulated crescendo, the duration of the whole sound is so short that the ear receives the impression that it is.

 Presystolic accentuation of the diastolic murmur.

 Pure presystolic murmur (most common).

 Diastolic murmur accentuated at the beginning and at the end of diastole.

 Pure diastolic murmur (least common).

The *pure presystolic murmur* is still more common in mitral stenosis. This is represented by a short crescendo sign, for there seems to be an actual pause between the diastolic tone and the murmur. Another modification consists of an *accentuation both at the beginning and at the end of the murmur*. This depends on the fact that the blood flows into the empty ventricle with greater rapidity at the beginning of diastole than during its middle period, when the difference of pressure between the auricle and ventricle has been to a great extent equalized. The last modification, the *pure diastolic murmur*, is the least common. The murmur follows the diastolic tone directly and then decreases in intensity without any subsequent presystolic accentuation. These four varieties of murmurs due to auriculoventricular stenosis can be illustrated by the preceding scheme.

All these modifications of the murmurs obviously depend upon the varying relations of the factors which influence the intensity of the murmur at each moment, *i. e.*, upon the degree of the stenosis and upon the rapidity of the blood-current. Therefore it is easily understood that

the great vessels from those of the auriculoventricular orifices.¹ The distinction may be designated symbolically thus:

Mitral and tricuspid insufficiency.

Aortic and pulmonary stenosis.

Only very close attention will detect this distinction. The closure time between the systolic tone and the murmur is so short (0.07 to 0.14 second, according to Martius²) that the interval cannot be detected as a distinct pause, but merely gives an impression of a somewhat less close connection between the murmur and the tone.

We need not fear confusion with a prediastolic murmur, because the latter is separated from the systolic tone by a longer pause, which is very plain; and because the succeeding diastolic tone follows so closely that it seems a part of the murmur.

Combinations of Murmurs from Multiple Valvular Lesions.—The same valve is frequently both narrowed and insufficient; hence we may meet with the following combinations of murmurs and tones:

Mitral insufficiency and stenosis	{	ftáfta ftáfta		
Tricuspid insufficiency and stenosis				
Aortic insufficiency and stenosis	{	taftáf taftáf		
Pulmonary insufficiency and stenosis				

When several valves are affected at the same time, the murmurs, if loud enough, may be transmitted over the entire heart, *e. g.*, with a combination of mitral and aortic insufficiency. In case the aortic murmur is transmitted to the apex, we may hear the following:

If there be a mitral stenosis in addition, we shall hear at the apex this modification:

Method of Localizing Murmurs in Multiple Valvular Lesions; Maximum and Minimum Points.—If several valves be diseased, and if one of them be doubly so, *i. e.*, with a stenosis and insufficiency, the murmurs will be transmitted in all directions, and the diagnostic picture will become so complicated that it may be very difficult to determine where each murmur really arises and where each one is to be heard merely by transmission. If, for example, a systolic murmur be heard at two orifices, *e. g.*, at the mitral and the aortic, it is very difficult to say whether the murmur at the aorta depends upon an aortic

¹ To detect this delay one must listen somewhat below the auscultation point for the arteries, in order to be sure of comparing the time of the systolic murmur with that of the first tone. Over the great vessels one may be easily confused by the "expulsion tone" (p. 322), which, of course, follows the murmurs of the great vessels without delay.

² Zeit. f. klin. Med., 1888, vol. xiii.

stenosis or is merely the transmitted mitral to make a mistake in either direction.

The best way to solve such a problem is chest chart, as in Fig. 159, the two murmurs, dulness, and then to decide, after very careful difference in the acoustic quality of the two

Should the two murmurs exhibit a slight example, one rough, the other smooth; one other blowing, it is probable that each murmur. But one must be somewhat cautious in deciding the quality as well as the intensity of a murmur slightly altered by transmission.

If no distinction in quality can be made, location will usually determine that the murmur

Fig. 159.—Diagram to illustrate the method of

intensity at one point than at another. Then will exist:

1. If the murmur be equally intense at both points, that a separate murmur arises at each spot, but generally deprives a murmur of some of its intensity might, however, be heard over the entire heart.

2. If the murmur be less intense at one or the other point, it is more likely to be transmitted from the aortic than over the mitral, generally be due to transmission. This is not as a faint murmur might arise from the aortic, from the mitral. To clear up the difficulty, listen from the one orifice to the other along the line. If the murmur *A* be merely transmitted from *M*, the intensity will increase from *A* to *M* (represented diagrammatically).

figure, whose breadth at each spot is a measure of the intensity of the murmur). But if, on the contrary, in auscultating from *A* to *M*, we find that the intensity of the murmur at first diminishes, reaches a minimum somewhere between *A* and *M*, then increases again up to a second maximum at *M* (Fig. 160, II), so that there are two maximal points, then, even though the murmur be weaker at *A* than at *M*, we can be sure that there are two different murmurs.

Supposing, as is so often the case, that the systolic murmur can be heard not only at *A* and *M*, but also (Fig. 160, III and IV) at *T* and *P* (tricuspid and pulmonary areas), the question arises whether at these four points we have to do with transmitted or original murmurs. Here we must again carefully heed the resonating quality and then auscultate along the lines *A P* and *A T*, *M T* and *M P*. The relations of in-

Fig. 160.—Diagram of the relations of transmission of cardiac murmurs. Maximum and minimum points.

tensity expressed in Fig. 160, III, show that the murmurs *P* and *T* are merely transmitted from *A* and *M*, whereas those in Fig. 160, IV, show that separate murmurs arise at *A*, *M*, and *T*, but that the murmur at *P* is only transmitted.

In this way the beginner learns to orient himself concerning the points of origin of murmurs in complicated valvular lesions. The important point is merely to proceed systematically. If both systolic and diastolic murmurs be present, first analyze the diastolic, not heeding the systolic, and later proceed in the same way with the systolic. With diastolic murmurs the problem is often simplified by remembering that modified diastolic murmurs, *i. e.*, presystolic or presystolic accented murmurs, can arise only at the auriculoventricular valves. Another almost constant law is that aortic murmurs, especially the systolic variety, are strongly transmitted to the neck vessels.

We hardly need mention that no importance should be attached to differences of intensity, because they may arise from causes other than those of the heart. The diagnosis of a combination of an aortic and a mitral murmur at the same phase of heart action requires especial attention. We find two plainly marked maximal points with an interval of 160, II, due to a single murmur; because murmurs are best transmitted to the surface wherever the left heart is nearest to the thoracic wall, viz., in the region of the aorta. At other places the superimposed right ventricle makes the diagnosis difficult. If a murmur be musical and of the same quality, this assumption is pretty safe. The resonating quality must be closely studied. The above-mentioned difficulties are insurmountable for auscultation alone to differentiate between the aortic and mitral murmurs; hence, all the other relations should be carefully studied.

Other Methods of Examination.—From what has been said above, it might appear that the various valvular lesions are perfectly differentiated by auscultation alone, but we shall see in the next section, murmurs of the same kind as to valvular lesions may occur without the existence of any alterations in the circulation, as well as the size of the heart, are quite as significant as the position of the heart. To localize the murmurs properly, as outlined above, requires an exact knowledge of the heart's size and position in the body. The point on the body is selected as a starting-point, but the heart is located in reference to the median line and the ribs, and hence for the localization of the murmurs other methods of examination, especially percussion. (See Individual Lesions.)

So-called Accidental Heart Murmurs.—Murmurs depend upon relative or functional insufficiency of the valves and are called *relative* or *functional* murmurs. They are due to a dilatation of the valvular ring or a lack of tone on the part of the papillary muscles (p. 330) and for various purposes we can consider them under the name of accidental murmurs, and whatever we have said thus far will apply to these functional murmurs.

Accidental murmurs, on the contrary, are those which are not due to the valvular mechanism, and, although acoustically distinguished from the murmurs of true valvular lesions, the valve is found to be perfectly normal.

They are frequently called *inorganic* or *functional* murmurs, but it seems to the author as incorrect a term as "inorganic," because murmurs may depend upon purely functional disturbance, while others have an anatomic origin. For example, anemic murmurs. Accidental murmurs have also been described as *inorganic*, because all accidental murmurs do not depend upon an anemic condition. The only way to escape this confusion is to distinguish sharply between *accidental murmurs*, and to separate relative from *accidental murmurs* and to classify these relative as the true organic murmurs.

Although the real origin of accidental murmurs is not known, the author will attempt to state his own views upon the subject.

Accidental murmurs are, with few exceptions, systolic, and are heard at all uncommon in health, and are then heard, for the most part, over the pulmonary artery. Autopsies furnish negative results, and the origin is conjectural. Acoustically, they are not essentially different from organic murmurs, therefore we assume that they, too, are current

formity with the laws applied to valvular defects. In the normal heart the experimental conditions (p. 327 et seq.) essential to valvular murmurs are surely present, and it is certainly more astonishing that ordinarily the blood flows through the heart without murmur than that murmurs may arise from perfectly normal hearts. Consider the irregularly formed inner surface of the ventricles, the resulting chances for friction, and the alteration in cross-section in the connecting portion between the ventricles and aorta or pulmonary artery. Indeed, it is almost more logical to attempt to explain how it is possible for tones, and not murmurs, to arise over the normal heart. Perhaps it is because the normal blood-current is not rapid enough to give rise to murmurs. Accidental murmurs would then depend upon an increased rapidity of the blood-current. The latter, in so far as it concerns systole, depends apparently upon the rapidity with which the ventricle contracts and upon the mass of blood to be emptied, *i. e.*, upon the amount of diastolic filling of the heart. Stolnikow¹ has demonstrated experimentally that the velocity of the blood-current may vary a great deal. In one experiment he found that the maximum was sixteen and one-half times greater than the minimum current velocity.

How completely the ventricle is filled during diastole appears to be of especial importance. For v. Frey and Krehl² found, in their experiments, that slowing the heart action, and thereby increasing the diastolic filling of the heart (vagus irritation or suffocation), only slightly prolongs the duration of the ventricular contraction. As a direct consequence, the pulse is slowed and the velocity of the current is increased. But, so far as the author knows, no direct experiments show that the current-velocity with low arterial pressure, *i. e.*, with slight resistance to systole, or with altered innervation of the heart, can be considerably accelerated without altering the frequency of the beat or the diastolic filling. Nevertheless, this does seem probable.

Accidental murmurs may therefore arise if the diastolic filling increase while the expulsion time remains constant, or if the ventricle contract more rapidly while the diastolic filling remains constant. The latter possibility seems possible, because accidental systolic murmurs, like many valvular murmurs, sometimes arise when the heart action has been excited or made rapid. But even so, this does not explain why they are ordinarily to be heard at the pulmonic area or over the left ventricle, and very rarely at the aortic area or over the right ventricle, unless it is on account of the varying anatomic configuration of the right and left ventricles and of the *conus arteriosus*.

They do not readily appear during diastole, because the velocity of the current during diastole is, on account of the longer duration of the latter and its weaker power, much less than the systolic. Besides, during diastole the current does not encounter any such alteration in the cross-section of the heart as it does during systole in its entrance into the aorta or pulmonary artery.³ Experience with mitral stenosis shows that the conditions in the interior of the heart are not especially favorable for the formation of diastolic murmurs, for frequently the diastolic murmur can be heard only during the presystolic accentuation of the auriculoventricular current (p. 335). Again, no other valvular lesion is so apt to run its course without a murmur as mitral stenosis (pp. 328 and 330).

Accidental murmurs appear most often when the ventricle contracts quickly; therefore we should expect them most frequently in strong people with good blood-pressure, and yet the reverse of this is true. To this objection the author can only reply that rapid contractions of the ventricle are in no way to be identified with high blood-pressure. Since the blood-pressure furnishes a resistance to the cardiac contraction, it is, on the contrary, probable that the ventricle would contract more rapidly with low pressure than with high. No special researches, so far as the author knows, have been made upon this point. To claim that because high blood-pressure increases the friction it favors murmur formation is the same as saying that the pressure, in so far as it does not influence the rapidity of current, has little or no effect upon murmur formation. (See the experiments of Weber, Heynsius, Nolet, and Thamm, pp. 327-329.)

The above explanation of accidental murmurs applies particularly to healthy individuals, in whom they very frequently occur. Lüthje has shown that, in the majority of children from ten to fourteen years of age, an obviously accidental systolic murmur can be heard at the pulmonic area. This may be due either to a quickened systole at that age, or to the difference in lumen between the ventricle and the pulmonary artery, which is especially marked in comparison with the size of the child, a condition to which Lüthje has given the name of "relative pulmonary

¹ Arch. f. Anat. u. Physiol., Physiologic Part, 1886.

² Ibid., 1890, No. 47.

³ The difference of cross-section between the veins leading to the heart and the auricle is much less than that between the distended ventricle and its efferent arteries.

stenosis." In either case the essential factor is the increased pulmonary artery. But this explanation also applies particularly to conditions in which accidental murmurs so frequently occur, fever, and anemia. In so far as general weakness is combined with high blood-pressure, its effect has been already discussed. In fever the rapid pulse and the decreased tension of the arteries, expressed in the usually lowered blood-pressure, would make the expulsion of the blood from the heart probable. Rüedi's description of the "tachogram" of the fever pulse also adds some weight. In anemia we must distinguish between the acute anemia of hemorrhages or oligochromemias; in the former the low blood-pressure and diminished cohesion or viscosity of the blood, probably occurs from the heart by lessening the resistance. Cohnheim proposes that anemia accelerates the blood-current, thus explaining the "systolic" character of the pulse. (See p. 350 et seq.) In chlorosis and other oligochromemias the cohesion or viscosity of the blood may also favor murmur formation. (See Law 4, p. 329).

The hypothesis advanced by many authors, that accidents occur upon an abnormal facility of vibration of the valves and of the walls of the heart, is to the author absolutely inexplicable. Whoever appreciates the difference between the much prolonged acoustic character of a murmur and the like character of a heart tone will hardly be satisfied with the idea of a tension of even a relaxed and irregularly vibrating membrane blowing murmur.

Special roughness of the walls through which the blood-current flows (p. 328), independent of valvular disturbances, does probably play a part in the origin of accidental murmurs, as in atheroma of the aorta and in the endocardium. This explanation evidently cannot apply to all cases of accidental murmurs, however, because accidental murmurs are only rarely heard at the aortic orifice; because the pulmonary artery is almost always free from such roughness; and because cases presenting accidental murmurs during life are very rare. In certain exceptional cases supposed accidents are nothing more than systolic vesicular breathing (p. 284).

So much for accidental systolic murmurs. The conditions of the heart itself are very unfavorable for producing such murmurs; but in rare cases a simple diastolic murmur is heard over the aorta, and so easily confused with an aortic regurgitation murmur, does appear without being dependent upon a valvular lesion. In anemic individuals¹ such a murmur is the diastolic accented portion of the venous hum, transmitted from the jugular veins to the adjoining portions of the innominate vein and vena cava superior to the heart (p. 350). By auscultation over the aorta upward to the jugular vein, one can generally recognize that the diastolic murmur, heard perhaps loudest over the aorta, merges above into the rhythmic diastolic accented portion of the continuous venous hum. According to the author's experience of both these types of accidental murmurs is limited to cases of oligochromemia (15 to 25 per cent. hemoglobin). This naturally facilitates the diagnosis.² In general, accidental murmurs are rare; when diastolic, they are always valvular.

The author recently saw a case where a weak diastolic murmur, plainly heard, though only during inspiration, led him to a diagnosis of aortic insufficiency, although the typical signs of a pectus celer (a rapid pulse, Duroziez's murmur, etc.) were absent. The autopsy

¹ Sahli, *Correspondenzbl. f. Schweizer Aerzte*, 1885.

² The author has, however, seen an instance of a very strong diastolic murmur referable to a venous hum when the hemoglobin was 15 per cent.

aortic insufficiency, but the presence of sharp, rough, chalky excrescences on the cusps of the valve, which evidently caused the murmur through eddies at the moment of diastolic stretching. So the accidental diastolic murmurs may be due to anatomic causes which do not affect the valvular function.

Another variety of accidental diastolic murmurs is the presystolic. They are rather rare, and have not before been described. They are probably caused by the presystolic acceleration of the blood-current. Like the murmur of mitral stenosis, with which they may be easily confused, they may be appreciated by palpation. They are due less to an anemic condition of the blood than to an increased contraction of the auricle, as is shown by the fact that they often occur without systolic murmurs or the venous hum.

The most practical points for distinguishing accidental from valvular murmurs may now be profitably reviewed. A murmur may be rightly considered accidental if nothing further point to a valvular lesion, *i. e.*, no preceding etiologic factor, such as inflammatory rheumatism, no abnormality of the pulse or of the circulation, no abnormality of the tone intensity, and no demonstrable dilatation of any cardiac chamber. Anemia, fever, atheroma, or a venous hum favors the diagnosis of an accidental murmur. Still, not every murmur heard over an anemic individual's heart is necessarily accidental; for relative insufficiencies are very often caused by anemic dilatation of the heart, and can be distinguished from anatomic valvular lesions only by the fact that they diminish or disappear with the improvement of the anemia. They are limited to the mitral and tricuspid, and are governed by the same diagnostic rules as the anatomic varieties. (See the Special Diagnosis of Mitral and Tricuspid Insufficiencies.) Location of the maximum point of a doubtful systolic murmur over the pulmonic valve argues in favor of its being accidental. Luthje called attention to the fact that such murmurs are usually stronger during expiration and may even disappear during inspiration. He makes use of this fact to support his theory that they are due to "relative pulmonary stenosis" (see p. 341), since during expiration the lumen of the pulmonary artery is decreased. The accidental murmurs of atheroma, in accordance with the anatomic seat of the atheroma, are usually localized at the aortic orifice, but also frequently at the apex. Though signifying no valvular lesion, they are really of serious import, because they depend upon anatomic changes which may later occasion fatal disturbances, with or without producing a valvular defect.

Simple accidental diastolic murmurs are exceedingly rare, are almost always associated with a venous hum, very often with a systolic murmur, and are generally confined to the most severe types of anemia (oligochromemia) (see, however, p. 342).

The purely accidental presystolic murmurs may be distinguished from the murmurs in auriculoventricular stenosis by: (1) the changes in size of the heart accompanying the latter, and (2) the hard quality of the tone following the murmur, due to the rigidity of the valves in these lesions. (See p. 318.) But confusion may result if the heart action be excited beyond the normal, and a strong contraction of the auricle, causing a presystolic murmur, precede or be combined with an increased contraction of the ventricle accentuating the systolic tone.

It is questionable whether accidental murmurs can really be distinguished by any acoustic peculiarity from valvular murmurs. In general

they are not so loud as the valvular (see p. 331); hear very loud accidental murmurs, and, convert murmurs, even in serious lesions. Similarly, the pansystolic murmur, its blowing, scraping, or musical nature, although the two latter characteristics generally abnormal configurations of the cardiac cavities or appear with purely accidental murmurs. The presence of a systolic murmur argues with some certainty against aortic regurgitation, and in favor of a mild insufficiency of the valve, which gives rise to the murmur only at the close of systole (see p. 336.) A prediastolic murmur, according to the classification, is accidental. (See p. 336.)

Influence of Breathing Upon Endocardial Murmurs.—Accidental, endocardial murmurs are influenced by the breathing in numerous ways. On the one hand, the extent to which the murmur is variable, depending upon the different phases of breathing, the breathing favors or hinders the current of blood through the heart.

So far as the overlapping of the lung is concerned, inspiration favors a murmur, because the heart is then more perfectly covered by the lung. On the contrary, expiration intensifies it. The effect of breathing upon the murmurs is more complicated. (See p. 134 et seq.) The entrance of blood into the right heart is always favored by inspiration. In the left heart, the rapidity of breathing. During rapid breathing the entrance of blood from the left heart, in consequence of the increased capacity of the pulmonary vessels and of the retention of more blood in the lungs, is hindered. With slow, deep respiration, however, this influence can be overcome. In the first half of inspiration, because in the second half the resistance in the pulmonary vessels diminishes the resistance in the pulmonary circulation, favor the passage of blood through to the left heart. Expiration favors the opposite way. It retards the blood-current through the heart, because it diminishes the negativity of the intrathoracic pressure. This influence is insignificant so long as expiration is merely passive. The effect of expiration depends upon whether it be quick or slow. In quick breathing the first part of expiration aids the flow by compressing the pulmonary vessels, while the second part hinders the filling of the left heart by the resistance in the pulmonary circulation. With quick breathing only the first effect of expiration is felt, and the filling of the left heart is not retarded. This influence is sometimes very plainly observed in valvular lesions. A decreased current through a cardiac orifice necessarily intensifies the murmur there. Very important points for differentiating right- and left-ventricular lesions will sometimes be furnished by carefully heeding the influence of quick breathing. It may be further mentioned that expiration directly diminishes the endocardial murmur by inhibiting the venous current. It also diminishes the murmur after an initial but transitory increase. This brief intensification is more suddenly exerted upon the pulmonary vessels.

Paracardial Murmurs

Under this title are included all murmurs synchronous with heart action which depend upon changes outside of the heart, i. e., in the pericardium or its immediate neighborhood—(1) the pericardial rub; (2) the pleuropericardial emphysematous murmur; (4) the pericardial friction sound.

Pericardial Rub.—Analogous to the pleural rub, it arises from the rubbing of the two pericardial surfaces by the deposition of inflammatory fibrinous or calcareous tubercles, by tumors, or by abnormal dryness (in chronic cases). Rubs present exactly the same acoustic varieties as

times finely creaking, sometimes crackling, sometimes the pericardial rubs, caused by an exceptionally slight roughness of the pericardium, are sometimes confused with endocardial murmurs. To make a diagnosis in such cases (as well as occasionally rough endocardial murmurs), it is very essential to pay attention to the phases of cardiac action. Endocardial murmurs correspond most accurately to phases of cardiac action, coinciding with the systolic or diastolic tone; pericardial murmurs, on the other hand, occur half-way between the tones, overstep the boundary between systole and diastole, or even quickly change phases, which endocardial murmurs never do. Sometimes pericardial murmurs are compared to a continuous scratching, which is merely intensified by the phases of cardiac activity. All this is perfectly comprehensible. We must consider that the point of time during which a pericardial murmur is to be heard depends much less upon the phase of cardiac action than upon the chance position of a roughness, which may change its form and extent within a few hours. In explaining the nature of the part of the pericardial murmur does not exactly tally with the timing of systole, Geigel noted that the greatest systolic murmur is heard on the surface of the heart, as compared to its pericardium, during the closure, but during the expulsion time of the heart, as the author believes, even at the termination of the latter

use of the sign Λ/Λ to describe and picture symbolically pericardial murmurs. The height of the teeth expresses the intensity of the murmur at a given moment. The following diagrams exhibit the nature of pericardial murmurs (see also p. 327):

Pericardial rub in the middle of systole and in the middle of diastole.

Pericardial rub systolic in time but also prolonged into diastole.

Continuous scraping pericardial rub, intensified in the middle of systole and in the middle of diastole.

Pericardial murmurs may arise from the entire pericardium, but the anterior surface of the heart is all that is usually examined, particularly of that portion uncovered by the lung or covered only by a thin pulmonary covering. These murmurs are most distinctly over the area of superficial cardiac dullness at the sternum, and they may frequently be felt there. Pericardial rubs depend in most cases upon inflammatory deposits, which may quickly change their character quickly, and disappear. The disappearance may depend (a) upon the retrogression of the inflammation; (b) upon the formation of adhesions, or (c) upon the formation of a fluid exudate, which separates the pericardial layers. A pericardial rub may, however, persist despite the effusion, for the fluid may be mostly collected in the posterior part of the pericardium and against the great vessels, and leave the rough visceral layer exposed anteriorly to grate upon the smooth epicardium. Again, even with large exudations, audible pericardial rubs may be heard from the inferior pericardium if the weight of the

heart have displaced the fluid and brought the two contact inferiorly.

The most trustworthy signs to distinguish pericardial murmurs are: the acoustic peculiarity of the former, their lack of correspondence to the cardiac phases. Pressure intensifies a rub, but does not affect a murmur. Bending posture in bed will accentuate a pericardial friction sound, change of position is required to affect an endocardial murmur. Pericardial murmurs can be influenced by the breathing in a special way. Besides the change of the pressure or pull acting on the pericardium, there must be considered the influence of breath therefore, upon the size of the heart, and the influence of the position of the heart, which varies with each phase of respiration. It is therefore, opposed. Considering the complexity of these relations, there is no any certain evidence for differentiating between endocardial murmurs. But Valsalva's experiment may sometimes be useful for differentiation. This experiment is performed in the following way: on inspiration the patient attempts an expiration with a closed

Heart covered with visceral pericardium

Pericardium

Fig. 161.—Two possibilities in pleuropericardial rubs. Diagrammatic representation of the chest.

time exerts strong abdominal pressure. This maneuver increases the intrathoracic pressure and prevents the entrance of the blood into the heart. The test is not suitable for very sick people. As a result, only a few pulse-beats grow fainter and often disappear, whereas the intensity of the rub is ordinarily increased, because the inflated lung presses against the pericardium. Faint pericardial murmurs are not transmitted with the rub. The rub is of the same intensity, because the latter are not only conveyed by the pericardium, but arise from each of the heart chambers bounding the pericardium. Faint pericardial murmurs can, however, be heard over the entire precordium. The test is useful in cases of pericarditis, on the one hand, and of endocarditis, on the other. In doubtful cases it can be utilized to clear up the diagnosis.

Pleuropericardial Rub (Extrapericardial; Pseudopericardial). This rub may be confused with pleural rubs when the latter arise from the friction of pleura costalis or pulmonalis, on the one hand, and of the heart, on the other, may be brought out by movements of the heart. They are called pleuropericardial, extrapericardial, or pseudopericardial, and appear chiefly near the left anterior pulmonary border.

The usual distinction mentioned for differentiating between ordinary pericardial rubs, viz., that the former exhibits a diastolic and respiratory, whereas the latter does not, is not entirely reliable. As we have seen, pericardial rubs are also affected by respiration.

points in differentiation is that the maximum intensity of true pericardial rubs is in the region of superficial cardiac dulness and over the sternum, whereas the extra-pericardial are best heard outside this area; again, the latter possess distinct cardiac and respiratory phases, while the former are less influenced by the respiration than by the heart action. If the deposit be quite circumscribed, holding the breath in extreme inspiration or expiration will decrease or abolish pleuropericardial rubs, but not easily true pericardial rubs. If this diminution or disappearance occur at the end of inspiration, the roughness will be situated upon the pleura pericardiaca, and so separated by the inflated lung edge from the corresponding roughness upon the pleura costalis (Fig. 161, *a*); whereas if at the end of expiration, the roughness will be upon the pleura pericardiaca and pleura pulmonalis, which are then no longer in contact (Fig. 161, *b*). True pericardial rubs are, on the contrary, usually intensified by holding the breath in extreme inspiration, especially if abdominal pressure be exerted (Valsalva's experiment, p. 346); but this is, of course, better appreciated over the superficial cardiac dulness, where the distended lung edge does not overlap the heart.

Precordial Emphysema Murmur.—If, from the rupture of alveoli, air escape along the interstitial pulmonary tissue to the hilum, and from there to the connective tissue of the anterior mediastinum, the superficial cardiac dulness will be diminished, the heart tones weakened, and resonating, crepitating, or metallic noises simulating râles may appear over the heart. They will be synchronous with the cardiac action, not with the respiration, and thus can be distinguished from the râles of interstitial emphysema. (See p. 301.) From the cardiac râles which may be heard over consolidations and cavities in the neighborhood of the heart, they can be differentiated by paying attention to the relations of the cardiac dulness, of the heart tones, and of the respiratory murmur, by the demonstration of signs of a pulmonary emphysema or of an emphysema of the skin, and by the consideration of other accompanying appearances and the history.

Pericardial Splashing.—If the pericardium contain both air and fluid, a characteristic splashing noise arises synchronously with and in consequence of the heart action. It will resemble what we hear by shaking a patient with pneumothorax and sometimes it will be metallic. The heart tones will then be diminished, or, by the resonance, sometimes increased (pp. 316 and 317), and in the latter event will present a metallic character. The cardiac dulness disappears in the recumbent posture, whereas in the sitting position the fluid pushes the deeper portion of the heart forward and occasions dulness. The heart action may produce similar splashing when there is a distended stomach, large cavities, or a pyopneumothorax, so that we must note the spots where the murmur is most intensely heard, the severe signs of pericarditis or pericardial perforation, the relations of the cardiac dulness, the exact conditions of the lungs, and the modifications, if any, produced by emptying and filling the stomach.

AUSCULTATION OF THE VESSELS

Both tones and murmurs can be heard over the vessels as well as over the heart. (See pp. 326 and 306 et seq. and p. 327 et seq. in regard to the definition of tones and murmurs and the discussion of their origin.) Some of them are transmitted from the heart. The stethoscope is always used to auscultate the vessels, and care should be taken to avoid any pressure.

AUSCULTATION OF THE ARTERIES

The *carotid* is auscultated at the angle of the jaw or at the inner edge of the sternocleidomastoid; the *subclavian*, above the clavicle, between it and the sternocleidomastoid, or below the clavicle, in the so-called "Mohrenheim's fossa," between the pectoralis major and the deltoid; the *brachial*, at the inner edge of the biceps, or at the bend of the elbow with a slightly extended arm; the *radial*, at the place where one ordinarily feels the pulse; the *femoral*, just below Poupart's ligament. Before auscultation the position of the artery should be determined by palpation.

NORMAL CONDITIONS

Two tones are heard normally over the carotid and over the femoral and over the abdominal aorta: the systolic tension of the vessel-walls, and a diastolic, the closure of the valves. Over the femoral and over the abdominal aorta nothing at all or a systolic tone. The small arteries are silent.

A so-called "pressure murmur" can be produced with some force upon the larger and even upon the smallest arteries. This is frequently a very loud, hissing, systolic murmur, the artificial stenosis of the artery. (See Auscultation) If strong enough pressure be applied to occlude the lumen of the artery, a "pure tone" is produced. Pressure tones and pressure murmurs are physiologic, so that, to bring out pathologic tones or murmurs, such as Duroziez's double murmur, we should never employ pressure over the vessels. A systolic murmur is sometimes heard in children from the third month to the sixth year, perhaps probably arises in the internal carotid,—exactly how and without diagnostic importance. [Fisher called attention to the fact that a systolic murmur is sometimes heard in children from the third month to the sixth year, perhaps probably arises in the internal carotid,—exactly how and without diagnostic importance. {Fisher called attention to the fact that a systolic murmur is sometimes heard in children from the third month to the sixth year, perhaps probably arises in the internal carotid,—exactly how and without diagnostic importance.}

PATHOLOGIC CONDITIONS

The diastolic, and still more the systolic, murmurs are often transmitted to the vessels of the neck. When the second sound is heard in aortic insufficiency, ordinarily but one systolic tone is heard over the vessels.

A systolic tone may be appreciated even over the femoral artery in the case of fever or of aortic insufficiency; and with the stethoscope over very small arteries, e. g., the radial [and the digitalis].

A rarer phenomenon is the double tone over the femoral artery, frequently in aortic insufficiency. Traube has explained this as a marked pulsus celer, the systolic tension and the diastolic tension each give a tone. But this is not applicable to the double tone in aortic insufficiency, when one, at least, of the tones may be of a low frequency. It has been suggested that in this case they are both due to the vibration of the auricle, the other, of the ventricle. But from the femoral vein for such an explanation to seem probable is reported by W. Schulz¹ from Minkowski's clinic, with both aortic insufficiency, the first tone was shown to be due to the ventricular pulse, the second to the pulse of the femoral artery, so that the first is the tricuspid, the second by the aortic, insufficiency. Therefore, hastened in comparison with the arterial, as the ventricular pulse during closure time, the arterial, not until after its closure. This has been noted, though very rarely, in chlorosis, pregnancy, and in aortic insufficiency. So far no satisfactory explanation for it in these cases.

The so-called Duroziez's double murmur is more common than the double femoral tone. If the pressure of the stethoscope over the brachial artery be gradually increased, the following series is obtained: without pressure the single or double arterial tone; with a little pressure, the normal systolic pressure murmur; with a further amount of pressure, the systolic murmur, followed by a fainter, diastolic murmur, finally, with still more pressure, the double murmur again. This second, diastolic murmur is caused by the transmission of the pulse through the artificial stenosis of the femoral. Aortic insufficiency furnish this double murmur if there should be a diastolic murmur. It may also be found with any pulsus celer, e. g., in hyperthyroidism, exophthalmic goiter. The author has heard it over the left lobular artery in inflammatory arterial liver pulse (see p. 198) by applying the stethoscope. A good deal of patience is required for the production of Duroziez's phenomenon, because it is a question of applying just the right amount of pressure.

A systolic murmur heard only over one subclavian artery hanging down and when no pressure is exerted by the stethoscope over the apex of the corresponding lung. Pleural effusion or a vessel sheath probably twist the artery, and so cause the murmur. Applies the thorax more closely against the stethoscope, the murmur disappears.

¹ W. Schulz, Deut. med. Woch., 1905, vi

to avoid any pressure. Sometimes, however, a subclavian murmur can be heard on both sides, more rarely on one side, in perfectly healthy people, and in many persons such a murmur may also be caused artificially by certain positions of the arms which compress the artery against the clavicle or against the subclavian and pectoralis minor muscles.

Systolic murmurs heard over the arteries, especially the carotids, without stethoscopic pressure, possess some diagnostic interest. They may arise in anemia in the same way as accidental heart murmurs (p. 340), and if not transmitted from the heart, they are often of the greatest importance in verifying the accidental character of a heart murmur in the same way as the venous hum (p. 349). The increase of the systolic blood-stream in the pulsus celer of aortic insufficiency, exophthalmic goiter, and chlorosis can cause murmurs over the arteries, independent of any transmission.

Localized arteriosclerosis will furnish a systolic murmur over an artery. A case of this kind was of considerable interest to the author. An old man presented a loud systolic murmur over the left carotid for months, and the diagnosis of an arteriosclerosis of that carotid was confirmed later by the onset of a left-sided cerebral thrombosis. Slight pressure of the stethoscope—not enough to cause a murmur in a normal artery—will sometimes bring out such an arteriosclerotic murmur. Litten recently emphasized its diagnostic importance, and described it as a phenomenon of palpation, under the name spurts—"Spritzen." It may be heard over the abdominal aorta as well as over the carotids.

Systolic and diastolic murmurs are frequently heard over the *enlarged thyroid* of exophthalmic goiter. The systolic are doubtless arterial, dependent upon a pulsus celer. It has not been determined whether the diastolic are arterial, and, like the second part of the Duroziez double murmur, a consequence of pulsus celer (in which case they are heard only with a certain pressure of the stethoscope); or whether they are the diastolic portion of venous murmurs (p. 350), isolated and strengthened because the veins are compressed or closed by the arteries during systole.

Any one who takes the trouble to auscultate the vessels frequently will hear sounds which have never been described and many which have not been thoroughly explained. The author mentions as an example the occurrence of three sounds in the carotid in cases of aortic insufficiency, which together give a rhythm completely analogous to the gallop rhythm of the heart, although such a rhythm is not present in that organ. It is probably produced by a combination of the transmitted first sound of the heart (intracardiac tension tone) with the two normal carotid tones, or by an arterial double tone with a transmitted diastolic tone from the aortic valve. In aortic insufficiency the author has also repeatedly heard a presystolic murmur, i. e., presystolic in reference to the local arterial sounds, which is probably produced by the marked increase in the velocity of the current (pulsus celer) preceding the systolic distention of the artery.

AUSCULTATION OF THE VEINS

TONES OVER THE VEINS

The blood flows through the veins normally without tones and without murmurs. The so-called venous hum is only very rarely heard in healthy individuals. The reflux blood-wave of the venous pulse in the greater veins (especially in the jugular vein and in the bulb) may cause a systolic tone, due to the relaxation of the valves and of the walls of the vein. This is particularly the case where the venous pulse is due to the strong pressure during regurgitation in a tricuspid insufficiency. In this case the valve tone over the bulb slightly precedes the systolic carotid tone. (See p. 199.)

For the so-called double venous tone over the femoral see p. 348.

MURMURS OVER THE VEINS; VENOUS HUM

Most venous murmurs are continuous, because the current in the veins varies so little in rapidity. The most important is the so-called

"venous hum," "nun's murmur," or "bruit c over the jugular vein very frequently in anemic a and not infrequently in health. It exhibits a c sound, sometimes blowing, sometimes humming ally whistling, with a rhythmic accentuation cor diastole, and to the phase of respiration. It is h
 • right side, over the carotid, in the angle between vicular portion of the sternocleidomastoid. Tl erect and hold his head straight, because the re ishes the intensity of the murmur and sometime Turning the head to the opposite side ordinarily Pressure of the stethoscope should be avoided, be exerted, the murmur practically always di carotid tone or an artificial murmur of the ste is heard. If faint, we can sometimes distinguish systolic, diastolic, and inspiratory portions of an interrupted murmur may be confused with a piratory murmur. Pressing very lightly with t ing the patient's head toward the opposite side the hum and transform the interrupted murmur and so clear up the diagnosis. The diastolic ac hum may be transmitted to the cardiac region i accidental murmur, but auscultating from the h generally distinguish the one from the other (p.

To explain the venous hum we must start occurs, although not exclusively, yet much t anemic individuals; and then we must turn to tl applying to the origin of murmurs in flowing c The two factors which are all important in prod are: (1) the presence of abnormal narrowings or and (2) the current rapidity. To explain the individuals the hypothesis has been advanced collapse in consequence of a diminished mass *bulbus* remains distended in virtue of its attachme An abnormally pronounced change of lumen tl vein and the bulb, and so produces the murmu certainly incorrect, because, in the first place, i uals in whom the venous hum is most common sition of a diminished blood-mass is quite errone second place, it is easy to see that in chlorosi generally well filled, and indeed often abnormal give up the hypothesis of a change of lumen at the jugular vein as an explanation of the muri attention to the second of the above-named fa rapidity. Have we any proof that anemic blo rapidity? Cohnheim's experiment in submittir artificially hydremic animal to direct observation blood actually flows more quickly than normal account of its diminished cohesion or viscosity dividuals usually exhibit a diminution of the their blood is not necessarily hydremic. Never estimations of their blood do show that it is ver

¹ Allg. Path., 1882, vol. i, p. 44

and, besides, it is perfectly conceivable that the cohesion or viscosity of anemic blood is diminished even without actual hydremia, and so the friction between the layer of blood against the vessel-wall and the circulating current would be diminished, and hence result in an increase of the current rapidity.¹ An increased current rapidity would naturally offset to some extent the disadvantage of a deficient hemoglobin. The explanation that the venous hum in anemic individuals depends upon an increased rapidity of the current is certainly the most probable. Of course, this theory assumes a normal change in lumen between the jugular vein and the bulb. The venous hum which is quite rarely observed in perfectly healthy individuals may reasonably be supposed to depend upon individual anatomic relations or conditions of distention of the vein sufficient to narrow its lumen and produce a murmur with normal current rapidity. The current rapidity of the blood may perhaps also vary within normal limits sufficiently to explain the venous hum in healthy individuals.

We explain the accentuation of the hum in the standing position by the influence of gravity upon the column of venous blood; it exercises suction, thereby narrows the vein, and so hastens the jugular blood-stream. The murmur is more plainly heard upon the right side, because the right jugular vein is almost a direct linear continuation of the right innominate vein; whereas the left jugular empties into the left innominate at an oblique angle, and so there is less obstacle to the current on the right side. By turning the head to the opposite side, the upper part of the vein is compressed by the sternocleidomastoid and omohyoid, hence this movement accentuates the venous hum. The accentuation due to the stethoscopic pressure needs no further explanation.

The rhythmic accentuation of the hum requires explanation. The inspiratory intensification is easily explained by the increased rapidity of the venous blood during inspiration. The explanation of the systolic and diastolic accentuation may be understood from an examination of the curve of the physiologic venous pulse (Fig. 109) or of the normal auricular pressure (Fig. 111), in which the two depressions x and y (x corresponding to systole of the ventricle, y to diastole) indicate an increase of rapidity in the venous blood-current.

Murmurs similar in character and origin to the venous hum may also be heard over the femoral vein and over a vascular goiter. In the latter they may be favored by irregularity of the lumen of the blood-vessels and the tortuosity of the veins.

The author attributes considerable diagnostic significance to the presence of a venous hum. If not absolutely pathognomonic, it at least, in suspected cases, suggests the presence of anemia. The demonstration of a venous hum confirms the diagnosis of an accidental heart murmur. A venous hum is also found in exophthalmic goiter, and is located most frequently over the goiter. Here, too, it probably depends upon an increased rapidity of blood-current.

¹ This theory is supported by the few investigations so far made concerning the viscosity of the blood.

AUSCULTATION OF THE

Excepting for the sounds heard over the pregnant uterus and placental bruits and cord murmurs), description of auscultation of the abdomen is generally barren of results (upon Auscultation of the Vessels (p. 347 et seq.) in the abdominal aorta.) Friction murmurs synchronous with peritoneal exudations over the liver or spleen (of considerable importance (perihepatic and perisplenic) claims that cases of cholelithiasis very frequently furnish a friction murmur over the region of the gall-bladder. Similar friction murmur is heard over the abdomen between roughened surfaces of the peritoneum appreciated by palpation than by auscultation, because of manipulation. In normal cases intestinal movements only very faint intestinal murmurs are to be heard. In cases of peristalsis the intestinal movements can sometimes be heard as so-called "borborygmi." Further, the coincident pressure over the abdominal cavity may, in moving a patient with percussion murmurs in the abdomen, frequently metallize the *succussio Hippocratis* (p. 301). They may be sonorous with the stethoscope, occasionally at a distance. They possess considerable diagnostic significance, since in the very diseases where a diagnosis of peritonitis is desired (for example, in ileus and where there is ordinarily an accumulation of air and fluid in the intestines capable of giving rise to the same sort of so-called "splashing noise" will be mentioned under Percussion. In the diagnosis of intestinal stenosis (from tumors) has been aided by the presence of a hissing or whistling sound sometimes at a distance even by the patient himself with the stethoscope, and sometimes by palpation. This is due to air being forced through a stenosis in the intestines. A patient will point to the best time for examination. (See the Abdomen, p. 257 et seq.)

Auscultation of the Esophagus.—(See the section on the Esophagus.)

PALPATION OF THE LUNGS

(In regard to the inspection of these parts of Respiration, p. 84 et seq.)

As has already been mentioned in several places (under Percussion Murmurs), palpation of the lungs is partly to confirm symptoms recognized by auscultation and partly to obtain independent results. Examining for fluctuation of the thorax, abnormal pulsations and abnormal expansion belong to the special province of palpation.

¹ The fetal heart tones are usually considered not to be heard before the thirteenth week of pregnancy, but Sarwey has shown that they may be heard as early as the thirteenth week, over a circumscribed deep area of the abdomen. To appreciate them, the bladder must be emptied, the patient must be quiet, and the examiner be possessed of normal hearing.

DETERMINATION OF FLUCTUATION AND CHANGES OF RESISTANCE IN THE THORAX

Fluctuation is obtained over superficial accumulations of pus or over a purulent exudate which has broken through the chest-wall and lies directly under the skin (a so-called *empyema necessitatis*). No real fluctuation can ever be appreciated over a serous or non-perforating purulent pleurisy because of the tension of the soft parts between the ribs.

But a kind of fluctuation or thrill (vibratory fluctuation) can be obtained over an effusion which extends from the front to the back of the thoracic cavity, by vigorously percussing the posterior thorax, and at the same time, with the other hand, palpating the front of the corresponding half of the thorax (bimanual palpation percussion). The appreciation of this phenomenon requires a very nice sense of touch. The author has noticed it in exceptional cases of sero- and pyopneumothorax, where the free mobility of the fluid permits a strong vibration wave. Here the phenomenon has some diagnostic importance, because the fluid lying beneath the lung cannot be demonstrated by percussion until it has reached a certain volume. (See p. 269.) The succussion felt in sero- and pyopneumothorax is an accentuation of the same phenomenon.

Palpation over pleuritic exudates and the different kinds of lung consolidations ordinarily detects an increase of resistance, which frequently the finger as plexor also appreciates during percussion.

ABNORMAL PULSATIONS IN THE REGION OF THE LUNGS AND PLEURA

Pulsation over the precordia will be described later (p. 355 et seq.). Where pulsating tumors have pushed the lungs aside and lie against the thorax, inspection or palpation, or both, may appreciate such pulsation over the chest. In marked mitral lesions, especially insufficiency, one can palpate, here and there through the thoracic wall, diffuse pulsations of the lungs. This can be appreciated better with the ear applied to a rigid stethoscope against the chest than with the hand. (See p. 356.) The phenomenon, due to an increased pulse in the pulmonary vessels, must be distinguished by its diffuse character from a mere mechanical heaving of the thorax transmitted from the heart. A pulmonary pulse may also be detected in insufficiency of the pulmonary valves (pulsus celer of the pulmonary artery). Pleural exudates may pulsate in the intercostal spaces (pulsating pleurisy) by transmitting the heart movements through the fluid to the intercostal spaces. This phenomenon is very rare, because the tension of the soft parts between the ribs is too great unless they and the pleura itself become softened and decomposed from the inflammation, and unless the intrapleuritic tension is diminished to equal that of the atmosphere. In short, empyemas, but only very few serous exudations, pulsate.

TESTING THE VOCAL (TACTILE) FREMITUS

By vocal (tactile) fremitus is meant the purring vibration appreciated by the hand placed upon the thorax of a person speaking or singing. It arises from the transmission of the vibrations of the glottis through the air in the trachea and bronchi to the thoracic wall. Physiologically, the louder and deeper the voice, the stronger the fremitus. The fremitus frequently cannot be appreciated in women with high voices, in very fat people, and in patients too sick to speak aloud. In children it is less distinct than in adults, and is often absent. The fremitus is strongest at the upper posterior parts of the thorax, over the great bronchi. From there downward and outward it is gradually diminished.

The fremitus is caused by the vibrations of the lungs and thorax set in motion by the transmitted vibrations from the glottis during speaking. What is felt then, is the vibrations of the deep pulmonary tones demonstrated by Sellig in his experi-

over pneumothorax also has exceptions, because if the exudate be small, the compressed lung increases the fremitus more than the exudate diminishes it. This is rare; but increased fremitus as well as bronchial breathing is common at the upper border of the pleuritic exudate, where the fluid layer is thin and wedge-shaped (see Fig. 145, I), whereas toward the base it is plainly weakened. (See Fig. 147, I.) Finally adhesions, if membranous or string-like, can transmit the fremitus to the surface through an exudate or through a pneumothorax.

One of the helpful methods of determining the level of the fluid in a pleuritic exudate is to map out accurately the line of demarcation between this increased and decreased fremitus. In tapping a chest we may sometimes avoid circumscribed adhesions within the area of a pleuritic effusion or of a pneumothorax by testing the fremitus.

Changes in the thoracic wall also influence the fremitus. Thickening of the wall, edema, and the like, diminish it. Over differently curved portions it varies under otherwise equal conditions, so that the relations of fremitus are not trustworthy in the scoliotic or deformed chest. Changes of elasticity of the thorax decidedly influence the fremitus, so that it may be diminished over contracted portions after pleurisy, even without any exudate or any considerable thickening of the pleura.

INSPECTION AND PALPATION OF THE HEART REGION (PRECORDIA)

We shall discuss these two methods of examination together, because they are so intimately related. Marked bulgings of the heart and of the pericardium have already been described in the section upon the Shape of the Thorax (p. 30).

HEART-BEAT AND APEX-BEAT

The heart-beat is the visible and palpable impact of the heart against the thorax; the heart apex-beat, more simply apex-beat, the portion confined to the neighborhood of the apex. Most diagnostic points are especially concerned with the apex-beat. To locate the heart-beat correctly, place the flat of the hand upon the precordia horizontally and close to the left parasternal line, with the fingers reaching to the left axillary line. The finger-tips may, at the same time, be utilized for more accurate localization of the apex-beat. If the examiner stand in front of the patient, he uses his right hand; if he stand behind the patient, the left hand. In women with large breasts the entire left mamma must be drawn up to the right. *Sp.* designates the apex-beat in our diagrams.

As Laënnec pointed out, the heart-beat can generally be appreciated better with the ear applied to the end of a rigid stethoscope than with the hand. As the skin of the ear is certainly not so sensitive to touch as that of the hand, this must be due to the vibrations of the rigid tube of the stethoscope caused by the heart-beat. This advantage can also often be gained if the hand, instead of the ear, be applied to the stethoscope. In ordinary palpation the contact of the two soft surfaces tends to dull

beat can change its position, moving to the left in left-sided positions, to the right in right-sided positions,¹ of the body or in the latter being completely obliterated by the overlying left lung. Bending the trunk forward in the erect posture, and so pushing the left lung edge somewhat aside, frequently brings out the apex-beat more plainly. This device is to be recommended in attempting to localize the left heart boundary when the apex-beat is rather indefinite. Of course, any lateral movement of the trunk should be avoided. Similarly, deep expiration will sometimes bring out the apex-beat, because the lung is thus more completely retracted. The Valsalva experiment, combining expiration with abdominal pressure, is not applicable, because it hinders the flow of venous blood to the heart, and so diminishes its size.

Stimulation to cardiac activity, either psychic stimulation or bodily exertion, intensifies and diffuses the apex-beat.

According to physiologists, the essential cause of the heart-beat is a projection of the heart apex and the neighboring portions of the anterior ventricular wall against the thoracic wall. Such projection is caused by the systolic change in the heart's shape. Martius' experiments demonstrated that the entire phenomenon of the heart-beat occurs within the systolic "closure time" when no blood has yet left the ventricle, but still remains there under higher tension. These experiments refuted all the other theories (recoil theory, theory of systolic stretching of the vessels). Under pathologic conditions certain other factors besides the change of form of the anterior ventricular wall must have some influence in the causation of circumscribed or diffuse pulsations over the precordia. (See p. 366 et seq.)

PATHOLOGIC DISLOCATION OF THE HEART-BEAT

The heart-beat may be displaced by an enlargement of the heart or by its dislocation.

The Heart-beat Influenced by Alterations in the Size of the Heart.—The left ventricle normally gives rise to the heart-beat; dilatation of its cavity in particular will, therefore, displace the apex-beat to the left, sometimes even out to the left axillary line. Dilatation of the right ventricle may also cause a marked displacement of the apex-beat to the left. (See p. 242.) Therefore we have no right to assume that a dilatation is limited to the left ventricle, because the apex-beat is displaced to the left, without paying special attention to all the other pathologic signs. If such a displacement be very marked, and if at the same time there be no increase of cardiac dulness to the right, we are justified in assuming a preponderating dilatation of the left ventricle. The heart apex rests closely against the surface of the diaphragm, running obliquely downward and to the left, so that in dilatation of the left ventricle an apex-beat pushed to the left will also usually be situated lower than normally. Dilatation of the right ventricle, on the contrary, merely dislocates the apex horizontally to the left, because an enlargement of the right ventricle, supported upon the diaphragm, tends to raise the heart apex. (See Fig. 120.) The dome of the diaphragm must necessarily follow this elevation under the influence of the air pressure from the abdomen. It is, nevertheless, doubtful if this distinction always ap-

¹ Wien. klin. therap. Woch., 1904, vol. xxi-xxiv, and Wien. klin. Woch., 1905, vol. xiv.

plies, because with marked dilatation of its chamber the right ventricle forms the apex itself, which must then drop downward in the direction of the heart's axis.

Simple hypertrophy of the cardiac muscle without dilatation is hardly ever sufficiently marked to occasion any noticeable dislocation of the apex-beat. (See p. 243 for exceptions to this statement.)

Only the most marked degrees of cardiac atrophy would be accompanied by or associated with a dislocation of the apex-beat.

Displacements of the Heart-beat from D
Heart.—(See the section upon Topographic Palpation, p. 249, seq.)

In *situs inversus* the apex-beat occupies the corresponding position on the opposite side. In *deformities of the thorax* the apex-beat may be placed in any direction. In *emphysema* it lies low and is often difficult to feel, although often the heart is so thoroughly covered by the lungs that it cannot be felt at all. In *unilateral retraction* of the lungs the heart may be drawn toward the affected side and generally upward on account of the high position of the diaphragm. In *hydrothorax* and *pneumothorax* cause a purely lateral dislocation of the apex-beat. (See p. 250.) If the dislocation be excessive, there may be a pendulum movement. If a left-sided effusion or pneumonia be around in front of the heart, the apex-beat may disappear. In right-sided effusions will sometimes crowd the apex-beat almost to the right side, and frequently to an abnormal height, in consequence of the pressure or pendulum movement, the left side of the diaphragm moving up and accompanying the apex. *Retraction of the left lung* by adhesions to the location of the mediastinum will accomplish a similar displacement. *Force of the intra-abdominal pressure* from *meteorism*, *ascites*, or *hernia* force the apex-beat upward, and frequently, in consequence of the pressure, a pendulum movement, somewhat to the left. (See p. 249)

INTENSIFICATION AND DIFFUSION OF THE APEX-BEAT

We appreciate the intensity of the apex-beat both by inspection and by palpation. If the palpating finger be raised quite vertically, the apex-beat is characterized as forcible or powerful. Under such conditions it is often diffused, shaking the entire precordia, although the apex-beat can almost always be determined by localizing the point of more decided elevation. Such a strong, well-defined apex-beat is nothing but an intensification of the apex-beat of normal conditions, because the strength of the beat varies so decidedly, under different logic conditions.

The apex-beat is increased pathologically (and the intensity is increased) by any *stimulated condition of heart action* (both *palpitation*, *exophthalmic goiter*, *acute and chronic toxic conditions*, *Cardiac dilatation*, even without any pronounced increase of cardiac activity, not only displaces and diffuses the apex-beat but also intensifies it. This seems anomalous; and the apex-beat with weakened pulse which is so often observed in *senile* heart lesions and in the so-called overexertion of the heart. *Martius'* cardiographic experiments proved that the intensity of the apex-beat during the closure time of systole, and that it is entirely proportional to the power with which the ventricle empties its contents.

the heart, the greater the change of its form at the closure time, and consequently the more marked the heart-beat, quite independent of the heart's power. In conditions of cardiac weakness the closure time is prolonged at the expense of the expulsion time; the heart only moderately diminishes during diastole; the heart-wall during the expulsion time moves from the thoracic wall only a little and quite slowly, and so the change of form during closure time is emphasized, and the heart-beat seems especially strong. Conversely, it is plain that when the heart's power improves in such a case the heart-beat will become weaker, because the expulsion of the blood begins earlier, is more complete, the heart becomes smaller more quickly during systole, and therefore recedes farther from the thoracic wall.

An accentuation and diffusion of the heart-beat frequently signifies merely a more extensive uncovering of the heart (pulmonary retraction, high position of the diaphragm, upward dislocation of the heart). (See p. 251.)

As has been said, an abnormally powerful apex-beat alone does not always signify cardiac hypertrophy. But one form of increased apex-beat, F. Müller's¹ so-called "heaving beat" (or, better, in the author's opinion, "slowly heaving apex-beat") admits of no doubt; it always implies cardiac hypertrophy. In this, although the heart action need not be violent, and is frequently not especially diffused, yet the heart apex lifts the palpating finger with pressure and with irresistible force. Very frequently also the heart action is slowed. These cases are characterized, according to Müller, by an exceptionally slow elevation of the cardiographic curve and by an increased systolic intracardial pressure, as well as by an increased resistance to systole. The slowness of the heaving depends upon the prolongation of the closure time, whereas the intensification of the heaving is the direct palpatory expression of increased intracardial pressure. The high intracardial pressure, *i. e.*, the resistance to the ventricular contraction, may depend upon a high arterial pressure or upon some opposition to ventricular emptying between the heart and the arteries, *e. g.*, an aortic stenosis. In any case it necessitates a cardiac hypertrophy to overcome the resistance, so that any permanently slow heaving apex-beat may be regarded as a safe sign of cardiac hypertrophy (primary hypertrophy). More importance should be attributed to the slowness of the heaving than to its force and extent, in order to prevent confusion with the increased beat in cardiac insufficiency, just mentioned above. In the recognition of cardiac hypertrophy a slow heaving heart-beat has about the same diagnostic significance as a persisting high-tension pulse.

It is not as yet certain whether other forms of ventricular hypertrophy which depend upon increased diastolic ventricular filling (the so-called secondary hypertrophy (see p. 382, 2) may eventually lead to the slow heaving apex-beat described above, or to a mere accentuation of the apex-beat. Increased resistance, which prolongs the closure time, does not seem to exist in the secondary hypertrophy depending upon dilatation. The effect must, however, be similar, because (according to Pascal's law of the hydraulic press) so long as the arterial pressure remains the same, the total ventricular burden increases in proportion to the inner surface of the ventricle. Future exact palpatory and cardiographic examinations must settle the question whether this kind of "overburdening" can produce the slowly heaving apex-beat, for evidently "overburdening" is not identical with increased arterial resistance.²

F. Müller's "vibrating apex-beat" differs both from the simple increased beat and from the slow heaving beat. Its impulse is more rapid and sudden, depending, according to Müller's experiments, upon a change in the form of cardiac stimulation. It is practically confined to subjective cardiac palpitation, especially the nervous form.

It would be of interest to determine whether, as is apparently the case, the di-

¹ Berlin. klin. Woch., 1895, No. 35, p. 757.

² O. Frank (Zeit. f. Biol., vol. xxxii) and Moritz (Deut. Arch. f. klin. Med., vol. lxxvi) call the burden of the ventricle caused by increased filling "burdening" ("Belastung"); and that caused by arterial resistance or tension, "overburdening." They show that the two factors have an entirely different importance in the heart activity. The original work must be consulted for this distinction.

versity in the apex-beat corresponds to a differing duration of the heart-beat, which is done by employing the method of measuring the duration of the heart-beat (See p. 311).

As soon as the major part of the heart is uncovered, the apex-beat is localized; but the entire precordia seems to vibrate with an undulation in which the different parts taken by the moving hand, the auricles, and great vessels can often be distinguished. (See p. 311.)

Compare p. 325 et seq. for the relation of the so-called diastolic recoil of the ventricular walls.

The "dome-shaped" apex-beat in aortic insufficiency should be noted. (See p. 398.)

WEAKENING OF THE HEART-BEAT

The heart-beat may be weakened or may entirely disappear. The effect may be produced by an *emphysematous lung* or by *pericardial or left-sided pleural effusions*; by *pneumothorax* or *collections of air in the anterior mediastinum*; by *adiposus*; by *edema* or *emphysema of the chest-wall*.

Its disappearance on account of a pericardial effusion is the most important of these causes. Before any diagnosis is drawn as to the presence of such an exudate, the position of the apex-beat in health should have been observed, because it has been typical before the patient's illness. Pericardial effusions always hide the apex-beat. The author once saw a case in which, in spite of a very large pericardial exudate, the apex-beat was still palpable. The apex of the heart was adherent to the parietal pericardium.

[A case of pneumonia at the City Hospital whose apex-beat was visible and slightly heaving to palpation in the axilla. At autopsy a "pericarditis with localized effusion" was found in the pericardium. The middle and lower portions of the pericardium were adherent to the heart, the upper and right portions were not. The right auricle was dilated and filled with several ounces of blood. On the left side of the heart, and directly over the left ventricle, a sac, somewhat smaller, contained several ounces of blood.]

Further, as the persistence of the pericardial friction is a sign of considerable pericardial effusion may collect and distend the pericardial cavity before it conceals the apex-beat. (See p. 311.)

A weakening or disappearance of the heart-beat may also be observed as a consequence of diminished cardiac power. These are mostly conditions of excessive cardiac weakness (e.g., heart failure). The heart-beat diminishes when the cardiac power is so weak that the alteration in shape of the heart during the systole is not sufficient to produce the heart-beat fails. But when the cardiac power is reached, the heart-beat will be vigorous or even increased. It is diminishing cardiac power.

The diminished tension of the radial pulse is a good guide to the condition of the cardiac power than the position of the apex-beat, especially if we are not familiar with the patient's normal position of the apex-beat.

ABNORMAL POSITION OF THE APEX-BEAT IN THE PRESENCE OF CARDIAC DULNESS

The apex-beat may lie inside of the cardiac dulness. The more clearly expressed, the deep and sometimes the more extensive the cardiac dulness may extend to the left beyond the

peculiarity may occur in a case of pericarditis, where the exudate is collected in the lateral portions of the sac and the apex-beat still persists, especially if the superficial dulness extend very far to the left of the beat. It is not, however, a pathognomonic sign of such a condition, for the apex-beat may lie within the deep cardiac dulness even under normal conditions (see p. 356), and within the superficial dulness under pathologic conditions other than that of pericarditis, *e. g.*, in mitral insufficiency. In this lesion the apex often belongs partly to the right heart in consequence of the hypertrophy and dilatation of the right ventricle. Again, the same sign may occur in all kinds of cardiac enlargements if an enlarged left ventricle had compressed the lung edge enough to make it atelectatic; the apex-beat would, of course, be further to the left than normal, but part of the increased dulness to the left of the apex-beat would be formed by the compressed lung.

SYSTOLIC RETRACTION AT THE APEX ; THE DIASTOLIC "REBOUND" (BRAUER)

This is sometimes observed instead of an apex-beat. It can be shown to be systolic by auscultating the heart.

If noted in a healthy individual, as it sometimes is, the sign cannot be perfectly explained. The author's theory, however, is as follows: The change of form of the heart normally causes a blow of the apex against the chest-wall; at the same time the sections of the heart lying above and within the apex retreat toward the interior of the thorax. Under physiologic conditions this would produce a palpable and visible systolic retraction of the thoracic section lying inside of the apex-beat. (See p. 356.) If, then, for some reason or other the apex-beat be absent, we might be tempted to speak of a systolic retraction of the heart apex; but in reality the apex would not be systolically retracted, but, rather, a part of the anterior cardiac wall lying above and inside it.

In some cases a systolic retraction at the apex or the precordia may be due to an adhesion of the parietal and visceral pericardium, and, generally, an adhesion of the pericardium to the pulmonary and costal pleura.

These cicatricial adhesions hinder the normal change in the shape of the heart during closure time and favor the contraction of the heart in the direction of its longer axis, which properly belongs to the expulsion time.¹ The apex is, therefore, retracted. Such a retraction of the apex causes a retraction of the thorax, even when there are no adhesions between the pericardium and the thoracic wall; for the space left by the shortening of the heart cannot be filled quickly enough by the lung margins to prevent the thoracic walls being forced inward by the atmospheric pressure. If the adhesions between the leaves of the pericardium be not cicatricial, however, there need be no anomaly in the apex-beat. In any case, pericardial adhesions cannot be diagnosed from this phenomenon with any certainty except when an apex-beat cannot be made out to the left of the retracted region, and when this region itself includes the greater part of the precordia. This diagnosis is, of course, much assisted by the history of a preceding pericarditis.

The cases of extensive adhesions between the pericardium and the thorax have recently assumed a practical importance, since Brauer has proved that this condition, which is usually accompanied by the signs of an excessively disturbed heart action and severe cardiac disease, may be greatly helped by "cardiolysis," which consists in the removal of the bony and cartilaginous parts of the thorax wall covering the heart. By this operation the heart is spared from expending a large part of its force in the active retraction of the thoracic wall, and is, therefore, greatly relieved. This procedure is, of course, useful only when there is actual adhesion between pericardium and chest-wall, not in simple adhesions between the leaves of the pericardium, which may cause similar symptoms. For the diagnosis of the former condition Brauer² emphasizes: (1) The wide-spread retraction of the chest-wall (ribs and lower

¹ See Tigerstedt, *Physiology of the Circulation*, 1893.

² Münch. med. Woch., 1902, p. 1072, Meeting of the naturhistorisch med. Verein in Heidelberg; Arch. f. klin. Chir., lxxi, Part 1, Transactions of the Congress for Internal Medicine, 1904 Brauer and Kuttner, Deut. med. Woch., 1906, No. 24, reports from the societies.

part of the sternum) and sometimes of the epigastrium; (2) the diastolic venous collapse (see Fig. 114, p. 198); and (3) the phenomenon which he calls the thoracic diastolic "rebound" (Schleudern). By this term he means the strong diastolic rebound of the chest retracted during systole. On auscultation this generally gives a clapping sound lagging after the normal second tone, so producing a kind of gallop rhythm. As the systolic retraction may indicate a simple adhesion of the leaves of the pericardium without involvement of the thorax, the thoracic rebound is the more important indication for operation. It shows that the chest is forced inward during systole, not simply by the outer atmospheric pressure, but also by an active pull from within the thorax, which relaxes during diastole and causes an elastic rebound. Brauer himself, however, has noted that the thoracic rebound with gallop rhythm is sometimes observed also in certain forms of hypertrophy of the heart in chronic nephritis, a fact which he explains by his theory of the mechanism of diastole. In these cases, to be sure, there is no systolic retraction. Still, as the apex is not always accessible to examination, and as the diagnosis would be doubtful, so the demonstration of the thoracic rebound is in many cases a very essential indication for cardiectomy.

DOUBLE HEART-BEAT; *CARDIA BIGEMINUS* *SYSTOLIA ALTERNANS*; *PSEUDOBIGEMINUS*

Two heart-beats may, under certain conditions, follow each other, and pairs or groups of two heart-beats be separated from each other by a pause (double stroke of the heart). There results one cardiac activity, distinguished by the titles: *cardia bigemina*, *systolia alternans*.¹ According to Unverricht,² these three names have no sharp boundary, and are, so to speak, genetically connected. They have been observed only in heart disease, especially in mitral and tricuspid insufficiency.

With *cardia bigemina* a peripheral arterial pulse occurs after each of the two heart-beats, and to the second of the double heart-beat, thus producing a double pulse (Figs. 60, 79, and 81). If there should be a venous pulse, it would also produce a distinct venous pulse. It is here repeated extra systoles, the arterial pulse of the extra systole being weaker than the regular pulse. (See p. 153.) It may also be due to the gallop rhythm (p. 159).

If the second contraction of the left heart becomes weaker and finally disappears, it finally disappears, perhaps from some obstacle or from some other cause, and if at the same time both contractions of the right heart are present, the result is *systolia alternans*. In this condition, then, the right heart beats alternately with the left heart. Such a condition was formerly diagnosed as *alternans*, where a double heart-beat was localized most plainly at the apex, where the radial pulse corresponded only to the first heart-beat, while the venous pulse in the neck corresponded to both beats.

Systolia alternans arises from hemisystole when the right heart becomes weaker and finally disappears. A peculiar condition might be determined in a ventricular septal defect, where a pulse unaccompanied by a venous pulse would correspond to the left heart (left), and the venous pulse unaccompanied by a pulse would correspond to the right heart (right). Here contraction alternates between the two sides of the heart.

The following scheme explains clearly the transition

		First heart-beat
<i>Cardia bigemina</i>	{ Right heart.	Effective
	{ Left heart.	Effective
<i>Hemisystole</i>	{ Right heart.	Effective
	{ Left heart.	Effective
<i>Systolia alternans</i>	{ Right heart.	Ineffective
	{ Left heart.	Effective

It is self-evident that valvular murmurs which could be heard in the heart would give great assistance in distinguishing these three forms of cardiac activity. The following picture has so cleverly pictured as modifications of one another.

¹ [For these terms the expressions, twin beat, half-beat, and double beat may be employed.—Ed.] ² Berlin. klin. Wochenschrift.

Most authors, however, agree with Riegel¹ and not with Unverricht. The former considers that the bigeminus is the only type of double heart-beat which has been conclusively demonstrated in man; and that the hemisystole, first described by v. Leyden,² and the systolia alternans assumed by Unverricht, in reality belong to the bigeminus.

That this is true, so far as hemisystole is concerned, is proved, according to these authors, by the fact that where an arterial pulse is not palpable for the second heart-beat, it can still be appreciated in the sphygmogram; and, according to Riegel's plausible theory, the venous pulse suffers less than the radial; because for a radial pulse it is necessary that the contraction of the left ventricle be still able to overcome the arterial blood-pressure. Here the so-called hemisystole should be regarded as a bigeminus in which the second heart-beat is so weak that it is noted only in the venous pulse and in the sphygmogram, but cannot be felt at the wrist—in other words, a "*pseudohemisystole*." Although physiologists have for a long time demonstrated hemisystole upon the exposed mammalian heart, thus far there has been too little clinical observation to determine whether it does actually appear in man. Unverricht drew his conclusions³ about systolia alternans, not from the alternation of the positive venous pulse with the radial pulse, but from less certain criteria, viz., the different location of heart tones, murmurs, and the beats in the two heart actions. The existence of systolia alternans must, therefore, be left undecided. (See p. 152.)

A double heart-beat may quickly alternate with normal heart activity. We do not yet know how to explain the cause of such a peculiarity, nor its prognostic significance.

INEFFECTUAL (FUTILE) HEART CONTRACTIONS

Quincke and Hochhaus⁴ designated by this expression peculiar cardiac contractions which occur in heart disease, and which are characterized by the insertion of a beat between normal contractions, sometimes periodically, sometimes quite irregularly, and especially by the disproportion between the increased intensity of the heart-beat and of the first tone, on the one hand, and the weakness of the corresponding arterial pulse on the other. *Further peculiarities of these futile contractions* are: the diastolic tone is weakened and premature; the abortive contraction itself seems premature, i. e., it follows an apparently shorter and precedes a longer diastole; the systolic and diastolic murmurs accompanying such ineffectual contractions are weakened or disappear; and the cardiogram may reveal changes which it is impossible to detail here. Not infrequently patients complain of these contractions as being painful or indefinitely unpleasant, or they may describe the sensation as that of a jolt or a blow.

This phenomenon without doubt generally depends upon premature or extra systoles. (See p. 153.) Only those extra systoles are "futile" (i. e., give the peculiarities just mentioned, particularly the failure of the radial pulse) which are sufficiently premature to fall within the time when the ventricle is not yet properly filled. When, sometimes, as Quincke and Hochhaus expressly noted, the futile contractions are not premature (i. e., are not extra systoles) they must be due to a disturbance of the contractile power. The subjective symptoms of a jolt or blow may easily be explained by a systole through which the heart does not empty itself.

CARDIOGRAPHY

The cardiograph is an apparatus which conducts the movements of the heart apex-beat, through hollow tubes, so as to represent them graphically upon a revolving drum. The resulting curves, so-called cardiograms, have already solved a series of very important questions in heart physiology.⁵

So far the method has not been so useful clinically on account of the manifold variations in the cardiograms due to differences in—(1) the exact spot examined; (2) the amount of overlapping lung; (3) the configuration of the individual thorax;

and (4) in pathologic cases, the size of the heart chambers. The results are, therefore, often difficult to interpret correctly.

The original apparatus was also somewhat cumbersome for practical use, but this difficulty has been obviated by the use of Jaquet's simplified sphygmocardiograph and Mackenzie's polygraph. (See p. 126.) For this especial purpose Jaquet has also devised another form of recording apparatus.¹ (See Fig. 162.)

It consists of a padded lead ring (*a*), covered with leather, which may be bent so as to conform to the surface to which it is applied. It is secured in place by a belt passing around the thorax and attached to *gg*, and by a strap fastened to *h*, passing

Fig. 162.—Jaquet's recording apparatus.

over the left shoulder, and attached to the belt at the back. The upright *d* can be raised or lowered by the screw *c*, and the pelotte, by the screw *f*. The pelotte should be placed as nearly as possible over the exact center of the apex-beat, and the proper pressure be attained by adjusting *c* and *f*. The simplification of the technic obtained by the modern apparatus possibly promises a more fruitful clinical use of the cardiogram in the future. Still, Mackenzie, who invented the apparatus, and who has made by far the most extensive practical use of it, points out the difficulty of a correct interpretation of the curves, owing to the great individual differences caused by variations in the point of application and the configuration of the individual thorax.

Fig. 163.—First type of cardiogram. During expulsion time the curve sinks suddenly after forming a short plateau. Simultaneous curves obtained from the apex-beat and the pulmonary artery in a consumptive with an advanced retraction of the left lung and exposure of the pulmonary artery (Mackenzie). That the second is really that of the pulmonary artery was proved by taking one of the carotid simultaneously. The letters correspond to those in Fig. 111. *D*, Closure time of systole; *E*, expulsion time; *P*, relaxation of ventricle; *G*, refilling of ventricle.

Figs. 164, 165, and 166 give some typical cardiograms illustrating some of the confusing variations. In the latter half of the upper curve in Fig. 165, we have a negative cardiogram, obtained by moving the pelotte away from the exact location of the apex-beat toward the edge of the sternum, so that the systolic raising of the apex is replaced by an apparent systolic retraction of the right ventricle. The radial curve below serves for orientation, and proves the negative character of the

¹It may also be used in examining other pulsations, *e. g.*, the liver pulse, the pulse of the abdominal aorta, the epigastric pulsation, etc.

re it is often difficult to determine the exact position of the apex—that a negative cardiogram might easily be obtained without its unless the radial or carotid pulse were also taken for purposes of

OTHER PULSATIONS IN THE PRE- NEIGHBORHOOD

The great vessels—aorta and pulmonary artery—are thoroughly covered by the sternum and the pulsations escape appreciation. Marked dilatation and retraction of the normally overlapping lung make them palpable. That of the pulmonary artery is in the left space; that of the aorta, in the second right space or the *diffuse aortic dilatation* caused by aortic dilatation are the more common causes of the aortic pulsations. These are generally responsible for the pulmonic pulsations. Dilated left auricle and left ventricle push the lungs forward. A vigorous hypertrophied right ventricle. (See Fig. 1.) Retracted by adhesions these pulsations may become normal-sized heart and great vessels. If the heart is small, slight pulsations of the anterior ventricular wall may be felt for pulsations of the great vessel trunks. In the case of aortic dilatation over which the heart-beat is palpable would be the pulsation felt earlier (*i. e.*, corresponding to the closure of the aortic valve) while in the latter instance the pulsation would be felt later. In case of an increased area of cardiac dullness, a powerful heaving character of a pulsation alone may show that the increased dullness is due to a widening of the arterial trunks, and not to a dilatation of the heart.

The systolic pulsation of an aortic aneurysm is felt over a considerable area, usually situated near the sternum. It is frequently visible as an expansile pulsation. It is, perhaps, better appreciated by the palpating hand. In the case, an aneurysm springing from the ascending aorta, the pulsation will generally be appreciable. It can be very plainly felt there as a pulsating tumor behind the top of the sternum. If an aneurysm of the descending aorta should show the pulsation falling within the area of cardiac dullness, therefore, a little delayed in comparison with the aortic pulsation point is particularly serviceable for distinguishing from an aneurysm of the ascending aorta, extending to the right of the sternum.

The left bronchus, which is straddled by the aorta, may transmit a pulsation of a large aneurysm, and will, in turn, transmit it to the trachea, and so to the larynx. By grasping the cricoid cartilage and forefinger of the right hand while facing the patient at the larynx this transmitted pulsation as a rhythmic tug, so-called *tracheal tug* (Oliver-Cardarelli phenomenon) is sometimes accentuated if the patient bend his head back and forth. This procedure may even make the tuggi-ness more pronounced. This should not be confused with the ordinary carotid pulsation of the arteries of the thyroid gland, neither of which is associated with head movement. The same sign has been plainly demonstrated in *mediastinal sarcoma* and in *dilatation of the arch of the aorta* that it can no longer be considered absolutely pathognomonic. The author has even observed the same sign in a man who was entirely normal, but in whom paralysis of the left recurrent laryngeal nerve suggested an aneurysm. The absence of other signs, how-

an x-ray shadow), the combination of paralysis of the corresponding vocal cord with that of the soft palate, and the quick recovery excluded the diagnosis of aneurysm, and the paralytic symptoms were assigned to a neuritic origin.

A short, sharp blow, corresponding to the *closure of the semilunar valves*, may be felt at the base of the heart whenever the aorta and pulmonary artery, uncovered by the lung, are exposed and situated directly behind the chest-wall. It is sometimes appreciable even without such uncovering; but never visible. Its brevity, which can be well appreciated by palpation, corresponds accurately to that of the auscultation sound of the second tone. It is to be felt most distinctly over the pulmonary artery in mitral lesions which are associated with an accentuated pulmonic second sound.

A *diffuse, feeble, systolic auricular vibration*, distinct from other cardiac pulsations, may sometimes be felt or seen at the base of the heart. It comes out especially plainly when a marked auricular dilatation from mitral or tricuspid insufficiency has pushed the lung aside. We feel, then, not auricular contraction, but auricular diastole, which in the valvular lesions mentioned above is intensified by the stasis or regurgitation at the mitral valve. In a gallop rhythm (see p. 325), the presystolic contraction of the auricle can sometimes be felt, provided the latter is not overlapped by too much of the lung.

A *systolic auriculoventricular valve shock*, the palpatory equivalent of the systolic valvular tone, and correspondingly brief, should not be confused with this auricular vibration. The former is felt in the region of the auriculoventricular valves to the right and left of the sternum, especially when marked cardiac dilatation pushes the lung aside. The ear against the stethoscope readily appreciates the difference between it and the actual heart-beat; it is not really heaving nor visible, and is much shorter and sharper than the latter.

An *epigastric pulsation*, a visible, palpable, pulsating shaking or lifting of the epigastrium, appears in emphysema. The diaphragm is low, the heart lies nearer to the epigastrium, the right ventricle is hypertrophied and may be dilated; hence the heart-beat is transmitted directly through the diaphragm to the epigastrium. A normal heart, if excited, sometimes causes an epigastric pulsation. Mackenzie has shown that the epigastric pulsation, in case it depends upon a low-placed hypertrophied right ventricle, is recorded by the cardiograph (see p. 365) as a systolic retraction, giving a negative cardiogram (see p. 365), while if it depend upon the left ventricle, the cardiogram is positive.

A pulsation of the abdominal aorta in a thin patient with retracted abdominal walls and partially filled intestines often resembles an epigastric pulsation, but a careful palpation of the abdominal aorta from below upward will generally distinguish them. This pulsation appears in the cardiogram to be almost synchronous with the radial pulse, and somewhat delayed in comparison with the apex-beat, which falls within the closure time. The same is true of the pulsation of aneurisms of the abdominal aorta.

Although we discussed *pulsation of the liver* in the section upon the Venous Pulse (see p. 192 et seq.), it should also be noted that an arterial pulse is sometimes felt over the liver. (See p. 198.) This occurs most frequently in aortic regurgitation as a result of the pulsus celer, and also in inflammatory conditions of the liver. The author has observed such

the arrangement of fat; the navel is depressed, because the connective tissue thereabout is so rigid that fat cannot be deposited. An attempt to grasp the panniculus adiposus between the fingers will solve any doubt. Percussion elicits a dullness, the intensity of which depends upon the thickness of the fat-layer. (See Fig. 2, p. 24.)

Edema of the abdominal wall presents the same retracted navel and may possibly be confused with a fat belly; but the almost constant existence of the edema elsewhere, its preponderance in the lateral and inferior portions as contrasted with the median deposition of fat, the pitting of the skin, and other clinical relations (p. 50) will solve any doubt.

Meteorism (tympanites) causes abdominal distention. It lessens or obliterates the umbilical depression unless the wall is thickened by edema or fat. The contour of the stomach or of the intestinal coils can frequently be seen through thin abdominal walls, especially when peristalsis is active or when the organs are dilated, particularly if the dilatation be dependent upon a stenotic obstruction in the digestive tract (*pyloric stenosis, ileus, intestinal tumors*). The intestinal movements in ileus are at first visibly increased; but later the distended coils, particularly those in the neighborhood of the obstruction, become paralyzed and immobile and occupy most of the abdominal surface. By noting through the abdominal wall the contour of an especially distended and completely immobile coil of intestine, the position of the obstruction can sometimes be determined. In very marked meteorism the difference in caliber between the large and the small intestine cannot be appreciated. The paralytic immobility of the visible intestinal contour and the absence of intestinal murmurs to auscultation are important signs for the diagnosis of *acute diffuse peritonitis*.

Free accumulation of air in the peritoneal cavity from perforation of the stomach or intestine is characterized by a uniform distention of the abdomen without visible stomach or intestinal contour.

A collection of free fluid also produces an apparently uniform distention of the abdomen. In the dorsal decubitus the fluid, when under no great tension, is mostly accumulated in the lateral portions, so that the abdomen seems proportionately broad. In case the fluid reaches so high, the navel (as contrasted with its position in meteorism) protrudes slightly. Percussion of an abdomen containing free fluid elicits a dullness of the dependent portions. (See p. 278.) This dullness shifts with change of position. Still more essential to the diagnosis of free fluid is the so-called *fluctuation wave* (see p. 373), which can sometimes, when the patient is moved, be appreciated, even by inspection, as a characteristic flopping. If the tension of the abdominal contents be increased, this flopping is not visible, but frequently the peculiar way in which a patient's movement makes the abdomen fall to one side like a heavy body shows the presence of fluid, in contrast to mere meteorism.

The presence of **distended veins in the abdominal wall** (p. 60 et seq.) aids in diagnosing the cause of the free fluid in the abdominal cavity. If they be limited to the sides of the abdominal wall (Fig. 20), and if an examination show that they conduct the blood from below upward, they present the type of collateral circulation observed most plainly in *thrombosis* of the *vena cava inferior*. In this case a part of the blood which should proceed through the *vena cava inferior* is deflected, and flows directly from the lower extremities,

through the veins of the anterior abdominal wall superior. Any fluid effusion in the abdominal cavity, the vena cava inferior enough to cause some obstruction of a collateral circulation is of slight value. If the effusion be very marked. Then it would point to an obstruction of the inferior vena cava. On the contrary (p. 61 et seq.) the veins which occupy more the middle of the abdomen radiate from the umbilicus in the form of a so-called "caput medusae" blood-current plainly flows in every direction. This would point to an anatomic obstruction of the inferior vena cava (*thrombosis of the portal vein*). It is suggested that this radiating arrangement is not a case of portal obstruction, but its median position of the blood-current away from the navel is of great diagnostic value. (See Fig. 21.) One might think that the presence of any effusion in the peritoneal cavity would produce a similar collateral circulation. Yet experience shows that this type of collateral circulation is practically limited to portal stasis from its compressing action on the liver and to *portal thrombosis*. This becomes possible when we realize that the small anastomotic branches, the ligaments of the vein and the area of the vena cava, which are essential to this collateral circulation, are just as much compressed by effusion as is the portal vein itself. (See p. 60 et seq.) This is something with the portal stasis in a limited sense, as in portal obstruction due to hepatic cirrhosis, or due to a thrombosis of the portal trunk near its entrance to the liver. This is then undertaken by the veins of the ligamentum teres, the serous covering of the liver, for they connect with the vena cava at a point above the obstruction (upstream).

Large ovarian tumors or *other abdominal tumors* are distinguished from effusions of free fluid by inspection, palpation, and percussion (p. 278 et seq.). With them the greatest degree of resistance is in the median line of the abdomen, rather than in the lateral portions. But all other methods of examination may be employed for a certain differentiation.

Enteroptosis presents to inspection a peculiar practical clinical picture. This condition depends on the relaxation of the abdominal walls and of the mesentery. It is observed in the female sex, and is due either to atrophy of the subperitoneal, submesenteric, and subcutaneous abdominal muscles, or, following a prolonged tension of the stretched abdominal wall. In the latter case there is almost always associated with the atrophy of the abdominal walls and of the abdominal contents, a spreading of the rectum. In consequence the abdominal organs are abnormally mobile. The kidneys in the erect posture are situated lower than in the recumbent posture. The kidney especially gradually draws down a mesentery, and thus becomes a movable, or even a genuine floating, kidney. The stomach and transverse colon may drop down into the lower abdomen. The weight of its contents causing it to frequently dilates the stomach. When the phys-

abdominal wall fails, the intestines become distended with gas. The skin of the abdomen becomes lean, withered, and frequently wrinkled; in patients who have borne children it is covered with striæ. The walls are so thin that the contour of the stomach and intestines, especially in the dorsal decubitus, can be made out very plainly. In the erect posture a veritable paunch is noticed, and through the gaping breach between the recti muscles a considerable portion of the abdominal contents projects like a hernia.

Empty intestines in **inanition**, *e. g.*, from starvation or esophageal stenosis, produce a very decided retraction of the abdomen. A similar appearance in tuberculous meningitis—the so-called “scaphoid belly”—is due to a contraction of the intestinal muscles, and perhaps of the abdominal muscles as well. Inspection sometimes reveals local prominences (cysts, tumors, enlargement of the abdominal organs) and their mobility with respiration.

PALPATION OF THE ABDOMEN

METHOD OF PALPATION

The first requisite is a thorough relaxation of the abdominal walls. Therefore, if his condition permit, place the patient in the dorsal decubitus, take away everything from under his head except a very thin pillow, and get him to breathe quietly, regularly, and without exerting abdominal pressure. Sometimes flexing the knees slightly will help to relax the abdominal walls. For palpating the lower portion of the abdomen it is frequently advantageous to raise the buttocks by putting a number of pillows under them, or to place the patient on an examining table in the Trendelenburg position. This frequently relaxes the abdominal walls to a marked degree, and pushes the abdominal organs toward the diaphragm, thus allowing the lower part of the abdomen to be more easily palpated. Considerable tension of the belly, if due to meteorism, can frequently be relieved and the examination be facilitated by first emptying the colon of feces and gas with the aid of a copious water enema. Great tension and extreme sensitiveness of the abdomen may necessitate the employment of anesthesia. It should, therefore, never be neglected in any serious and doubtful case if there be a question of an operation, as the absolutely relaxed walls under anesthesia enable the examiner to make a more thorough examination.¹

The physician himself can prevent a reflex spasm of the abdominal muscles by his method of palpation. If his hands be cold, they should be warmed before he touches the patient's belly. He should not palpate with the finger-tips, but always with the flat of the hand, with gradually increasing pressure. All hurried movements annoy the patient, render the examination difficult, and are therefore to be avoided. The more superficial should precede deeper palpation, because the former is less disagreeable to the patient. The expiratory retraction of the abdominal walls enables one to press the hand gradually deeper. At first the hand should be placed upon the spot to be examined, and

¹ According to the author's view, an examination under anesthesia should be limited to the determination of some condition which might require a decided change in therapy. He emphasizes this because such examinations and exploratory laparotomies, the former sometimes not less dangerous than the latter to the patient's well-being, are often abused.

left there quietly during both inspiration and expiration; the parts under the hand move during the respiration; this should be noted; and only after this procedure should the procedure be made use of to feel the entire abdominal surface. In the presence of affections it is a good rule to begin with the periumbilical region to gain the patient's confidence and distracting his attention. This should be recommended in examining children. The patient should rest as comfortably as possible, otherwise the results will be impaired. Bimanual palpation frequently furnishes the most reliable results. One hand placed upon the lateral or anterior surface presses the parts against the other hand in the rectum.

In all difficult cases it is of decided advantage to change the positions of the body, *e. g.*, in the dorsal, the left lateral, the erect, the knee-chest posture, the Trendelenburg posture, and the Trendelenburg posture.

Rubbing the skin of the abdomen with powdered chalk frequently facilitates an examination. The fingers slip over the skin more readily, and the results are increased. This device makes palpation less difficult to the patient, and is, therefore, to be recommended. A frequently helpful expedient for relaxing the patient during palpation is immersing the patient in a hot bath.

Jerky or interrupted palpation [*"dipping."*] is frequently useful for certain purposes. The palpating hand is placed upon the surface of the abdomen to be examined; then quite passive movements are employed with the flat of the hand or sometimes the fingers. This method may demonstrate the collection of fluid, the presence of deeply placed solid masses covered by fluid, or palpation does not reach. In favorable cases movable parts, if movable, seem to strike the palpating hand, and excites a great wave movement in the fluid.

Intermittent palpation is employed in obstetric examinations—*"mentum"* of the fetal head. *"Dipping"* can be employed to demonstrate enlargement of the liver or of the spleen, a distended gall-bladder, and for palpating an abdominal fluid where ordinary palpation as well as percussion is not sufficient.

An important rule in palpating the abdomen is to be cautious, since roughness can very easily do harm in inflammatory affections.

GENERAL RESULTS OF ABDOMINAL PALPATION

Abdominal palpation should appreciate the resistance in the belly (both of the walls and of the palpable boundaries of the organs, their position, and any local resistance and tumors. Palpation completes, and corrects the results of inspection. It detects fat-accumulation, of edema in the abdominal cavity, or of meteorism. Interruption of the "fluctuation wave."—Ed.] is the best method for detecting fluid. One hand strikes a short, sharp blow upon the dependent portion where the fluid is suspected.

present, the other hand, upon a diametrically opposite spot of the abdomen, will then feel a plain wave shock. *Fluctuation*, in the ordinary sense of the word (*i. e.*, the transmission of slow pressure movements through the abdomen), cannot be relied upon to demonstrate fluid in the belly, because the normal intestines filled with air fluctuate in that sense. The distinct transmission of short blows is, on the contrary, quite characteristic of the presence of fluid rather than of gas, because the phenomenon requires a considerable mass and there is the delay of inertia in the moved substance.

Enteroptosis presents to palpation an abnormal thinness and flabbiness of the abdominal walls and hyperesthesia. The organs may all be palpated and bounded just as if there were no covering. Tense intestinal coils and a stomach distended with gas are often much more readily outlined by palpation than by percussion, on account of their firm resistance, like that of an air-cushion. Contracted intestinal loops feel like tubes, varying in size from the little finger to the thumb. They are generally movable enough to be rolled under the finger. The "haustra" of the large intestines can sometimes be plainly felt. In palpating abdominal organs their respiratory mobility is always important. (See Special Palpatory Relations of Certain Abdominal Affections.)

In palpating *tumors* or *pathologic resistances* we should carefully heed their position, their form, their size, the possibility of outlining their boundaries, their consistence (solid, hard, compact, elastic, fluctuating¹), the character of their surface (smooth, nodular), and their sensitiveness to pressure. We should then determine from what organ the tumor arises; whether it is covered by the stomach or by the intestines, etc. Artificial distention of the stomach or colon will often clear up this part of the examination. The stomach can be distended either by means of an effervescing powder or by inflation through a stomach-tube. (See Gastric Examination.) The colon is most conveniently inflated by means of [an ordinary Davidson syringe.—ED.]² Inflation will conceal from inspection, percussion, and palpation tumors which are situated behind the stomach or colon or in their posterior walls.

In determining *tenderness* very gentle palpation is first employed. If this produce no pain, more force is used. We should then determine whether there is sensitiveness to quiet and regular pressure or only to displacement of parts, for in many cases the tenderness is produced only by a blow, not by mere pressure. This is frequently the case in peritonitis. After we have demonstrated the existence of tenderness, we should always attempt to differentiate at what depth it is situated. By pinching up the skin or the entire abdominal wall in a fold we can readily prove whether it is merely a sensitiveness of the abdominal wall and of the skin or whether it arises from the abdominal contents. If we can determine a hyperalgesia of the unaltered skin, even to light touch or to pinprick, over the painful area in any doubtful painful affection of the abdominal contents, the pain in question is not alone peripheral (organic pain), but is either

¹ There is a special sort of fluctuation, the so-called "hydatid thrill," which is sometimes appreciated over echinococcus cysts by striking a blow upon one spot of the tumor. The thrill proceeds from the impact of the daughter cysts.

² It is frequently necessary beforehand to cleanse and empty the rectum thoroughly with a copious enema of water.

increased or exclusively caused by central stimulation the patient's suffering depends upon more than is limited to the abdominal contents. (See Examination System; Hyperalgesic Zones of the Skin in Diseases of the Organs, p. 983.) Cutaneous hyperalgesia plays an important role in the diagnosis of pseudoperityphilitis. This is especially in the ileocecal region, which often arises psychically, and the attention has been more and more attracted to the value of such psychic ileocecal pain is frequently responsible for the necessity of an operation. The sensitiveness to pressure in the abdominal wall for the most part, to these hyperalgesic irradiations corresponds. As was formerly supposed, correspond to the position of the tumor. The usual position is but slightly accessible to direct epigastric pressure point directly under the xiphoid process. Pressure points to the left of spinous processes of the thorax are to be regarded as neuralgic pressure points in which there is a radiating increased irritability in the area of the corresponding segments of the spinal cord.

SOURCES OF ERROR IN PALPATING THE ABDOMEN

The abdominal walls frequently resist palpation by reflex tension which no device can control, even under the most favorable conditions. The individual parts of the abdominal wall, especially the muscular bellies and tendinous bands, offer considerable resistance both in their tension and in their resistance to pressure. Sometimes they produce the impression of circumscribed areas of pathologic resistances. This is even more striking in the case of contraction of the abdominal muscles lying directly over the tumor. When the abdominal pressure becomes reflexly contracted and more tense (muscle rigidity), abdominal pressure will facilitate the recognition of such areas. For example, coughing will make their contour still plainer. The abdominal pressure during coughing or during increased abdominal pressure is a very useful means of differentiating whether tumors are situated beneath or within the abdominal wall. Tension of the abdominal muscles from coughing will cause the resistance to palpation of the abdominal wall. If situated in the wall itself, a tumor will either become more distinct, or, at least, remains palpable during coughing. The lobules of fat of the panniculus abdominalis may simulate a nodular growth within the abdomen. The same is true of the umbilicus. The same is used to prevent this source of error. Contracted muscles of the abdominal wall often plainly felt through thin abdominal walls, as in the case of the rectus abdominis. (See p. 373.) The cylindric contracted transverse colon of the abdomen is often mistaken for a tumor of the stomach or for a scirrhous degenerated and contracted omentum. The lack of mobility of the transverse colon, which we can ordinarily feel by the palpating finger, the palpable recognition of the tumor, and the results gained by the distention of the colon from air, will generally prevent a mistake.

Fecal tumors frequently cause an error in diagnosis. Accumulations of feces in the colon, sometimes in the form of large masses, sometimes in that of smaller tumors arranged like a string of beads. Constipation usually accom-

ena; but fecal tumors are sometimes observed even in patients whose bowels move daily. They present a peculiar, somewhat doughy consistence: they can frequently be crumbled into smaller pieces; they are often arranged characteristically, like a string of beads; and their position in the course of the colon and the sigmoid flexure is suggestive. The coincidence of constipation, the lack of serious symptoms, and the disappearance of the masses after purgatives or enemata should prevent an error in diagnosis. Epigastric or aortic pulsations may sometimes simulate a tumor [or an aneurysm.—Ed.] (p. 367). If such a pulsation be transmitted to a tumor, the latter might be taken for a pulsating tumor. Remembering this should be sufficient to prevent the mistake.

SPECIAL RESULTS OF PALPATION IN CERTAIN AFFECTIONS OF THE ABDOMEN AND ITS ORGANS

Inflammatory exudates are appreciated by the examiner as imperfectly or perfectly circumscribed tumor-like resistances. They are almost always passive and immovable with respiration. *Perityphlitic exudations* are inflammatory exudations characterized by their peculiar location about the cecum. In spite of the presence of pus (e. g., appendicular perforation and abscess) they may exhibit a very firm consistence, but this distinction no longer has any practical value, since the so-called "stercoral" tumors are now known to be inflammatory exudates and phlegmonous infiltration, quite frequently even collections of pus. It is now believed that all inflammatory conditions of the cecal region are of the same character, are infectious and usually start in the appendix or cecum, and that their differences are only those of degree.¹ A firm tumor (as contrasted with a diffuse resistance) is very likely due to the formation of thick adhesions and localized infiltration and exudation. Such forms are also frequently perforative, despite their generally favorable outcome. The long-continued persistence of such a tumor, despite the lack of all serious phenomena, is one of the most trustworthy signs of an abscess which for the time being remains quiescent. Wherever, despite the most serious symptoms, the

¹ See the author's paper upon "The Pathology and Treatment of Typhlitis," der Behandlungen des XIII. Cong. f. inn. Med. in München, 1895, Bergmann, Wiesbaden.

Although in this article the author helped to discredit the then fully current conception of a stercoral typhlitis, and to urge operation for certain forms of perityphlitis, he by no means intended to assist the tendency toward neglecting diagnosis in cases of ileocecal pain. So far has this tendency now carried the profession that every pain in that region is looked upon indiscriminately as a sign of appendicitis. And yet it is certainly true that simple constipation, wind colic, diffuse enteritis—all can cause pain located in the ileocecal region. Intestinal pain is due to increased pressure of the intestinal contents. (See Nothnagel, *Zur Pathogenese der Kolik*, Arch. f. Verdauungs-Krankheiten, vol. xi, and Meltzer, *Bemerkungen über Gastralgia, Magenkolik und Kolik in allgemeinen*, New York German Med. Soc., April 6, 1903; reprinted in Arch. f. Verdauungs-Krankheiten.) The presence of the ileocecal valve prevents this increased pressure from being equalized in the cecum, in contrast to other sections of the intestine, as the intestinal contents can move only in one direction, and even in that direction their progress is frequently prevented by impacted feces. Hence, intestinal pain is apt to center in the ileocecal region. The present generation of practitioners have in general been taught to judge the question of appendicitis from a one-sided point of view, ignoring physiology in favor of surgery. Hence these important facts of pathologic physiology, and the frequent picture of ileocecal pain with no involvement of the appendix have completely vanished from the mind of the majority of practitioners. This explains the present blind zeal for operation, inconceivable to the scientific minded physician, and disgracing the name of medical science. Year after year countless appendices are removed when no appendicitis nor, in general, any abnormal condition of the appendix is found. We are in the midst of a raging epidemic on the part of both the laity and the profession, which coming decades will deride with the same justice with which we in our day condemn the bloody vampire of the Broussais school with their routine blood-letting.

acterized by an elastic consistence, and sometimes also by a change in size coinciding with the alterations in the amount of urine.

Tumors of the liver and of the *spleen* are characterized by their position and by their relation to organ boundaries, which we can definitely palpate and percuss, and also by their marked mobility with respiration.

Tumors of the mesenteric and retroperitoneal glands are characterized chiefly by their multiplicity; by the rounded contour of the individual tumors; by their deep position underneath the intestines, recognized by percussion as well as by palpation; and by their etiology, for they are generally metastatic. *Tuberculous retroperitoneal and mesenteric glands* present similar conditions. *Tuberculous tumors of the peritoneum* are palpated as nodular or irregularly defined resistances. The *tuberculous infiltrated and retracted omentum* presents a very characteristic picture. It can be felt as a knobbed cord between the xiphoid cartilage and the navel running horizontally and superficially. It may sometimes closely simulate an enlarged and uneven liver ("tuberculous pseudoliver"). *Tumors of the bladder* and *tumors growing out from the pelvis* are characterized by their position, which can be more accurately established by means of a rectal or vaginal examination.

Fig. 168.—Riedel's projection of the liver in cholelithiasis.

Diffuse enlargements or *low position of the liver* are recognized quite easily by the shape of the resistance; the determination of the sharp edge of the liver; and the respiratory mobility. The diminution in the size of the liver in *acute yellow atrophy* and in *cirrhosis* can safely be diagnosed by palpation and percussion only where the previous position of the liver edge has been known. The normal liver is, however, not always palpable, depending upon the thickness of the abdominal covering and upon the extent of the respiratory excursions. In palpating the liver border it is often very important to recognize the normal notch at the insertion of the ligamentum teres. *Enlargement of the gall-bladder* from biliary stasis, gall-stones, or empyema may be characteristically localized by palpating just to the right of this notch, where we can frequently very plainly follow the sharp edge of the liver above the rounded or gourd-shaped tumor, the gall-bladder. Occasionally we can feel one very large or countless small gall-stones inclosed in the enlarged gall-bladder of a gall-stone affection. Any hard places are usually caused by an inflammatory thickening of the wall or by carcinomatous infiltration, which so frequently follows old cases of cholelithiasis. "*Dipping*" (i. e., jerky palpation) over the enlarged gall-bladder will sometimes bring out a crepitation or grating of the gall-stones upon one another. If we cannot feel the enlarged gall-bladder in cholelithiasis, we frequently can feel a peculiar, tongue-like projection of the

position furnishes better results. In palpating the spleen, stand, if possible, upon the right side of the patient, place the palpating right hand as flat as possible upon the left hypochondrium, with the fingers at the costal margin, and with each expiration gradually exert slightly more pressure and attempt to feel the edge of the spleen during deep inspiration. Especially in typhoid fever a splenic enlargement can be felt only at the end of deep inspiration. In very sick cases the best method is from time to time to encourage one or two deep inspirations, because frequently repeated respiratory efforts tire the patient and his breathing becomes very superficial. Trying to feel the spleen with the fingers hooked in under the rib margin from above ordinarily produces such vigorous reflex abdominal contraction that nothing can be felt. Correct splenic palpation requires much practice. It is a good preparation for abdominal palpation. [Most beginners are apt to employ too great force in palpating for the splenic edge.—Ed.]

Large left-sided pleural effusions sometimes, though exceptionally, dislocate the spleen sufficiently for it to be palpable. Ferber explains this peculiarity (his opinion is supported by postmortem researches) in this way: Such effusions push the spleen so that the posterosuperior end reaches forward, the inferior end, back-

Fig. 170.—Splenic tumor of leukemia.

ward; hence the long axis of the spleen assumes at first a vertical position, and finally a direction from in front and above backward and downward. In other cases the upper edge of the spleen is turned so toward the interior by the inferior convexity of the diaphragm that the splenic surface lies no longer vertically, but horizontally. Both results are thoroughly unfavorable for palpation, and, besides, the respiratory mobility is lost, because the diaphragm on that side is almost stationary. What we often mistake for the spleen in these cases is the bulging of the depressed diaphragm running parallel to the costal border. (See Fig. 147, I, p. 268.)

(Compare the section on Examination of the Stomach in regard to the palpability of the spleen in certain cases of gastric dilatation.)

A distended bladder (see Fig. 171 upon next page) is easy enough to recognize after it has once been felt. It may be confused with the pregnant uterus, with other enlargements of the uterus, with ovarian tumors, and with inflammatory exudates. To differentiate, we must utilize other methods of examination, *e. g.*, by vagina, and especially examination after catheterization.

A peritoneal friction may be appreciable to palpation over the different organs or over tumors of the abdomen. The friction can be felt as a rough grating with

the respiratory and palpatory moving of the parts. It auscultation. (See p. 352.) These friction murmurs can surface (tumor surface), but in most of the cases they deposition of fibrin. Splenic enlargement (in leukemia splenic, and cholelithiasis to perihepatic, friction murmur

FOUNDATIONS OF THE PATHOLOGICAL VALVULAR LESION

EFFECT OF VALVULAR LESIONS UPON THE MECHANICS OF COMPENSATION; LAWS GOVERNING RELATIONS OF SIZE OF THE INDIVIDUAL VALVULAR LESIONS

To understand the symptom-complex of any appreciate: the fundamental factors of physical

the preceding sections), the effect of each individual valvular defect upon the circulation, and the anatomic changes and the modifications of the functions of the individual heart chambers which are produced by the wonderful efforts for compensation. To avoid repetition, the following introduction contains the fundamental factors of the pathologic physiology of valvular lesions:

Any valvular lesion, whether a stenosis or an insufficiency, from the moment of its origin leads to certain alterations in the distribution of pressure upon each side of the affected valve. If the body and the heart itself did not possess a series of powerful compensatory aids to improve this relation of altered pressure, then every serious valvular lesion at its very inception would not only cause serious general disturbances of circulation, but very soon prove fatal. Experience shows that neither is the case. Without compensation the blood in every valvular lesion would be collected behind the diseased valve, and peripherally the blood-mass and the arterial pressure would gradually diminish more and more. The heart's reserve power prevents to a certain extent such a dangerous condition; the heart sections lying behind the injured valve work harder, diminish the blood-stasis, furnish enough blood to the peripheral arteries, and so prevent a dangerous fall of the arterial pressure. The reserve power is utilized in stenosis to overcome the obstacle; whereas in insufficiency it must force more blood forward during the succeeding phase through the injured valve. Rosenbach and Cohnheim produced artificial valvular lesions in animals, and proved that immediately after the onset of a lesion an increase of cardiac work prevented any serious consequences to the circulation. To effect this increased work permanently, anatomic changes in the heart are bound to ensue within a short time. These consist in *hypertrophies* and *dilatations* of the different chambers.

Under the head of *Compensation* we include the entire complex, increased filling and increased work of certain heart chambers, with their resulting dilatation and hypertrophy, *i. e.*, the sum of all those functional and anatomic changes which, in spite of serious lesions of the valvular apparatus, correct the fault up to a certain point, render life possible, and also warrant a condition of circulation endurable to the patient. Compensation, however, does not make the circulation normal, because the pressure behind the valve must be kept abnormally high, so that despite the disturbance the essentials for the circulation may be preserved. What compensation accomplishes is only to keep the pressure in the systemic arteries, capillaries, and veins within the physiologic limits, so that the current rapidity and volume of the circulation are approximately normal, and so that in consequence the most essential bodily functions can be performed without marked subjective symptoms. To fulfil all these requirements, the compensatory changes must naturally prevent the increase of pressure from working backward behind the next valve. Therefore in mitral lesions the most perfect compensation is one which will not increase the blood-pressure nor the volume of blood within the pulmonary circulation. Such patients suffer from dyspnea in case of any unusual demands upon the respiration. (See p. 92.)

This conception of compensation is only a relative one. In this connection another point should be mentioned. In stenoses of the auriculoventricular orifices

and in all insufficiencies¹ compensation does not prevent the general circulation from being situated behind the obstacle. The general circulation therefore suffers from a blood deficit, because the mass distends these congested chambers is of no avail. We therefore find that in these cases the circulation adapts itself to such a condition by increasing the pressure in the arterial vascular system, or whether, in order to make up for the deficit, the pressure in the venous system gradually increases. Unless the latter be the case, the defect is equivalent to a venesection and the part of the vascular system which is not dammed.

Dilatations and hypertrophies of individual heart chambers are governed by very simple physiologic laws, and from them any valvular lesion can be determined.

These laws are as follows:

1. Any heart chamber which suffers an increase in pressure has an augmented resistance to overcome and hypertrophies, i. e., corresponding to the greater amount of work, increases in thickness, without an increase in volume (primary hypertrophy).² (For certain exceptions see note.)

2. Every heart chamber which suffers an increase in volume (primary dilatation, dilatation compensatory dilatation). In order that the pressure be preserved, it is necessary for the resulting dilatation to be completely or very nearly so. Therefore it must be hypertrophied, because, as is well known, the work done is the product of the systolic volume by the pressure. As a result of this increase of cardiac work in each chamber its walls must eventually hypertrophy. This hypertrophy is apparent either in an increase in volume or, perhaps more probably, in a preserved thickness despite the dilatation.³

¹ The stenoses of the arterial orifices behave differently from valvular lesions where, during the stage of compensation, the diastolic pressure above the obstacle is increased, but there is no damming behind. There are also cases where the stenosis from the beginning is situated in a chamber above the lesion.

² The pathologists designate this kind of hypertrophy as *simple hypertrophy*, the included cavity is not enlarged as *simple hypertrophy*, *eccentric hypertrophy*, in which the cavity and the thickness of the walls increase together (see the following note). It does not seem easy to explain why the cardiac cavity does not always result as a consequence of the increase of its walls, for it can be proved mathematically, as we have seen mentally, that the cavity must increase in size coincidently with the increase of its walls. For example, suppose we place one of the chambers of a heart (Deut. med. Woch., 1897, No. 1), filled with some oily solution of muriatic acid and let it stand at an incubator temperature. The wall will gradually swell, and, since there can be no increase in volume, the surface will become indented, the wall sinking in. Now, how can we explain the different behavior in the heart? The answer is that there results a pure simple hypertrophy without an increase in volume because a growth of muscular fibers in the layers of the wall of the cavity is made mechanically impossible by the maximum pressure. This compression persists as long as a ventricle for which hypertrophy are present (i. e., increased resistance to tension) has of the reserve power at its disposal to contract completely.

³ What the author has called *secondary hypertrophy* the pathologists designate as *eccentric hypertrophy*.

3. Where the conditions for *primary hypertrophy* and *primary dilatation* occur coincidentally, hypertrophy and dilatation of the heart chamber in question may take place entirely independently of each other.

4. In addition to the *primary dilatation* mentioned above (Law 2), a so-called *secondary dilatation* may arise. The latter, for the same reasons as under Law 2, occurs if a heart chamber without any primary increase in its blood-supply be not able to contract fully, and so during diastole suffers an increased pressure, because the blood entering finds a certain amount of blood left there from the preceding diastole. This type of dilatation depending upon an incomplete systole is called a *secondary* or *paralytic dilatation*. It has no compensatory significance, as contrasted with the type of dilatation described under Law 2, which is, as we shall see from examples, of decided value to the circulation, and therefore fittingly called a *compensatory dilatation*.

Dilatations due to incomplete systole are most frequently met with in the so-called compensatory disturbances of heart lesions (see below). Here, despite the variation in their causation, they all possess a common attribute in that they all depend upon cardiac weakness, with the result that systole becomes weaker and the systemic arteries are less completely filled than during compensation. By the appearance of secondary or paralytic dilatations these disturbances of compensation can alter the primary picture of compensated valvular lesions in manifold ways. Such secondary alterations may disappear when the heart has regained its complete power, or they may remain permanent despite the subsidence of the compensatory disturbance, *e. g.*, the secondary dilatation of the hypertrophied right ventricle in mitral insufficiency. The persistence of such secondary alterations may perhaps be explained by the fact that, if a heart chamber has once been stretched by a paralytic dilatation, its recovery is rendered difficult, because the opposition to systolic contraction increases in proportion to the increase in its contents (because the work of a heart chamber in contracting is equal to the product of its pulse volume by the opposed pressure). If this opposition to systole caused by the dilatation reach such a grade that the stretched cardiac muscle, in spite of its secondary hypertrophy, can no longer contract fully and so equalize the dilatation, but is limited to propelling the normal volume of blood from the diastolic position, then the heart chamber in question will finally, to a certain extent, become decidedly dilated with a hypertrophied wall. In this way the paralytic dilatation will persist anatomically fixed, notwithstanding the fact that the compensatory disturbance has receded.

Even without a preceding disturbance in compensation, similar dilatations sometimes affect those parts of the heart which, according to Law 1, should be purely hypertrophied, because they have been subjected, not to greater filling, but merely to increased systolic pressure. The most frequent instance is again the dilatation of the right ventricle in mitral insufficiency, which may occur even without any disturbance in compensation. Such dilatations are, in a measure, related to the paralytic dilatations after a compensatory disturbance which are described above as anatomically fixed. The fact that such a disturbance in compensation does not precede can probably be explained by assuming that the dilatation in these cases begins quite gradually, not from an acute loss of cardiac power, but in consequence of a slow

increase in the obstacle, which has gone on in the absence of a complete systole, and by further dilatation is rendered comparatively harmless. The heart develops step by step with it, and becomes adapted to the new conditions.

Another conception of such primary dilatation of the heart which are simply under higher pressure is that it is a ventricle subjected to an excessive systolic pressure when its musculature is stretched, just as a muscle is when an increase in the distance between its two extremities increases its initial tension. This is, however, true only up to a point, for the power of the skeletal muscle diminishes. This point is reached in the skeletal muscles, is sometimes known as "Fick's point." Fick would not venture to claim that in this respect the heart is different from the skeletal muscles, nor that this explanation is sufficient. Such an increase of power in the stretched muscle is not in accordance with the theory that such a dilated chamber is incapable of doing more work. For the work done by the stretched muscle depends on the distance through which it is moved. Here the pressure is increased, so that the power exerted by it, is increased, even if the distance through which it is moved, represented by the degree of closure, is not increased. This is incompatible to the view that dilatation beyond a certain point is of no use to the heart muscle. For it has already been stated that if subjected to too great a degree of tension, its power is diminished.

After we have reviewed these latter conceptions, we must modify Law 1, for an increased resistance of the heart chamber can produce a pure hypertrophy as long as this resistance does not exceed a certain limit. As this point is passed, incomplete systole, and not a pure hypertrophy of the dilated heart chamber, is the result. To explain the peculiarity that in some cases a pure hypertrophy, and in other cases a pure dilatation, is the result of the heart.

It has often been questioned whether such a dilatation is alytic dilatation and later anatomically fixed, or whether it is again completely in spite of their increased content. It is not possible to produce incomplete systoles. An objection to this is that, if no stasis occur, provided a circulation is maintained, the heart chambers will be more extensively dilated by the excess of the propelled blood, and so they will do correspondingly more work during systole, and for this reason will be permanently dilated and at the same time will result in an entirely purposeless enlargement of the heart, and besides in a purposeless increase of the work of the heart (compensation). It is not possible definitely and a priori to say under conditions of the circulation can really occur. A teleologic conception of the process of compensation, which is a purposeless increase of the work of the heart which augment with increasing resistance will furnish an explanation for the fact that in the case of a pure hypertrophy, sooner or later, to a definite cardiac insufficiency, the lesion does not increase.

To decide whether such a heart chamber which contracts incompletely depends very closely upon the resistance of the heart, under physiologic conditions, is it sometimes also incomplete? This controversy can, according to our present knowledge, be answered only in the affirmative. A heart which contracts completely or almost completely if the resistance is normal. It should act in the same way so long as the resistance is not too great.

are only slightly increased. Aside from the teleologic significance which the latter condition possesses for the preservation of the circulation even under somewhat more difficult conditions, the author sees a clinical demonstration in proof of it in the fundamental Law No. 1, *i. e.*, with a mere systolic increase of work a ventricle will ordinarily merely hypertrophy without any dilatation. As soon as the slightest increase in opposition prevents the ventricle from contracting completely, it must always dilate, *e. g.*, a dilatation of the right ventricle must, therefore, always occur in mitral insufficiency. With more pronounced opposition to its emptying the heart seems to react with a diminished systole (concurrent in by Marey,¹ Dreser,² Tigerstedt and Johansson,³ and O. Frank⁴). The question resolves itself, then, into whether we are to consider this latter phenomenon as a physiologic reaction or as a consequence of a pathologic condition—a weakening of the heart. Personally, in agreement with O. Frank and Moritz,⁵ the author considers it a physiologic reaction. His reasons are: the skeletal muscles behave quite analogously; the phenomenon is frequently of great teleologic significance for assisting the heart and the arteries with high blood-pressure; and it has been experimentally demonstrated that such a heart, as soon as the opposition has been reduced, recovers itself immediately and contracts again completely. If we believe that incomplete systoles occur physiologically, it seems perfectly conceivable and entirely within physiologic facts that a cardiac chamber enlarged by paralytic dilatation permanently contracts incompletely.

A certain number of autopsies upon patients with valvular lesions seem to argue against the above-mentioned laws. We must remember, however, that the relations of size of the chambers in the heart of the cadaver differ essentially from those in the living heart, because the phase in which each cardiac chamber is paralyzed (systolic, diastolic arrest) is of especial significance. The degree of rigor mortis of the heart is very rarely heeded at autopsy, although it would be a valuable study to determine the time of onset of the heart-muscle rigor and its influence upon the size of the heart chamber. Moreover, we have no right to compare the relations of the heart of valvular disease at autopsy with the relations of the compensated valvular lesion, because disturbances of compensation usually affect patients with valvular disease some little time before their death, and so the relations of the size of the heart may be very much changed. We will mention this again in the special description of individual valvular lesions.

In reality, therefore, in order to determine the relations of size of the individual heart chambers during good compensation we should utilize only autopsies upon patients with valvular lesions who have died suddenly from some intercurrent trouble, and not those upon patients whose death is directly dependent upon their heart lesion. Even in the former the autopsy finding is not actually and necessarily the same as during life.

It is doubtful whether the Röntgen rays will furnish us more trustworthy results about these relationships.

Compensatory anatomic alterations of the heart are usually permanent, because the valvular lesion itself rarely improves and because life depends upon the maintenance of compensation. Compensatory changes may increase in the course of years, because valvular lesions are often progressive. Where the valvular lesion itself is capable of retrogression, the compensatory changes, too, may retrograde to a slight extent or even completely disappear. These are extremely rare cases.

Dilatations and hypertrophies proceed in which occurs, and this necessity can be put the above-mentioned laws.

COMPENSATORY DISTURBANCES

A valvular lesion, thanks to the so-called hypertrophy and dilatation of individual years produce no marked symptoms, but the general circulation will be affected more or less when compensatory contrivances fail. We then speak of "decompensation." The causes of these disturbances are, on the one hand, an increase in the opposition to the flow of blood by the valvular lesion, or the appearance of new lesions (arteriosclerosis, nephritis); or, on the other hand, a weakness of the heart muscle, which recent investigations have shown depends upon inflammatory alterations of the myocardium. The process in valvular lesions is frequently produced by a process which goes on similarly in other circulations, and does not depend upon an injured valve. For a long time the heart remains compensated by the hypertrophy and dilatation until finally disturbances in compensation occur. The degree of compensation depends upon the relation between the circulatory obstacles and the power of the heart. In either an absolute diminution of cardiac power or an increase in the resistance, exhibited by a diminution of the systolic pressure in the ventricular chambers. The heart begins to work with less efficiency, and the residual blood in all or in a certain one of its ventricles increases. Under Individual Valvular Lesions the compensation of the heart is affected by secondary or tertiary disturbances. If the general stasis ensues in consequence of diminished cardiac power, the condition affects the right heart more than the left, and is localized more in the systemic than in the pulmonary circulation. *vice versa*. Thus, the clinical picture with valvular lesions has, however, considerable variations, and presents varied obstacles to the circulation, and

¹ A hypertrophied heart, even under the best of all ordinary demands upon it, often fails under the most favorable conditions. In other words, even a well-compensated heart lesion, in certain circumstances, implies a loss of power. This arises from the fact that there is not to any increase in the number of muscle-fiber substance, but always only to a thickening of the fibers. The sarcoplasm (Albrecht, *Der Herzmuskel*, Berlin, 1894) is merely the nutritive part of the muscle, and the chamber, therefore, gains no absolute increase of power. The extra supply of sarcoplasm, to maintain for a long time, Albrecht considers that this increased activity is not permanent but is merely the reserve force possessed by a normal heart, which can be used permanently only by a hypertrophied heart. The fact that a heart put out when extra work is put on it, is thus readily fatigued, and the heart is at best normal, and a greater or less part of its power is consumed in overcoming the resistance to circulation. This fraction of the total force is, therefore, no longer available for the demands upon the heart.

whether the diminution of heart power proceeds from the left or from the right heart. Only in rare individual cases do these disturbances vary decidedly. This uniformity probably depends upon the fact that the coronary arteries are injured as much in paralysis of the right as in paralysis of the left heart, so that the entire heart finally shares in the paralysis. This usually uniform clinical picture of compensatory disturbance may be described as follows: The filling of the systemic capillaries diminishes. The distention of the veins and the venous pressure increase. The circulation is slowed by diminution in the blood-supply. Cyanosis and dyspnea ensue. Edema and other dropsical accumulations are added. The urinary excretion is diminished and the urine frequently contains albumin. The causes of these appearances are discussed in the sections on edema, dyspnea, cyanosis, amount of urine, and albuminuria. The pulse frequently varies; it is very often accelerated, as if the heart attempted to overcome to some extent its fault of incomplete contraction by great frequency of contraction. This depends probably upon accelerator stimulation, due to the insufficient circulation. The heart action is frequently very irregular and produces the impression of overstimulation. This is probably due to a disturbance in the automatism of the damaged heart. Very pronounced irregularity has been designated quite properly *delirium cordis*. Neither great rapidity nor irregularity of the pulse necessarily accompanies compensatory disturbances. Like the other symptoms, one or the other of them may be lacking or very much less pronounced. The single constant factor in compensatory disturbances is the diminished cardiac power and the insufficient systole. Quite an important diagnostic sign of disturbed compensation in a valvular lesion with an audible murmur is that this murmur may become fainter and perhaps inaudible on account of the diminution in the current rapidity within the heart. On the other hand, a dilatation of the ventricle caused by the disturbed compensation may produce a murmur where one was not audible before, or bring one out very much more distinctly, due to a relative insufficiency of the auriculo-ventricular valve (p. 329 et seq.), which is superimposed upon the original lesion. This subject has already been discussed under Cardiac Murmurs. From evident reasons, the heart tones are frequently weaker in disturbed compensation. In patients with disturbed compensation we sometimes find a relatively tense pulse (*i. e.*, high arterial pressure), which would seem to argue against our explanation that compensatory disturbances depend essentially upon insufficient cardiac power. As a matter of fact, the difficulty vanishes when we remember that the work of the left ventricle does not depend merely upon the arterial pressure, but is measured by the product of the arterial pressure by the volume of blood emptied during systole, and that with marked arterial resistance even a very small systole may produce high arterial pressure. The author calls such a condition "high-pressure stasis,"¹ in contrast with the more frequent "low-pressure stasis," where arterial pressure is diminished by the disturbed compensation. "High-pressure stasis" occurs especially in circulatory disturbances associated with arteriosclerosis or chronic nephritis or in stasis from any cause, in case the tone of the vessels is increased by dyspnea.

¹ See Sahli, *Herzmittel und Vasomotorenmittel*, Cong. f. inn. Med., Berlin, 1901.

INDIVIDUAL VALVULAR

The alterations in size of the different heart hypertrophies) which occur in individuals explained perfectly by a thorough comprehension have been discussed in the preceding pages compensation and the disturbances of the same. By the number of the law which explains them will be mentioned in the text. (See p. 38) and that his comprehension of these laws will give the hydraulic diagram given at the beginning will find represented there the alterations in each heart chamber. The signs employed in these diagrams is given under should consult pages 309 to 340 in order to understand the results of physical examination, and he should recall (p. 217 et seq.) that the superficial, the red the deep cardiac, dullness signate the point upon the skeleton for the percussion wedges represent the murmurs, and the the murmur. Near the blunt end of the wedge the diminuendo murmur; the sign < represents the tones at the apex of the heart and over the heart vessels) the tones are represented by the the murmur is determined by its position, and the accentuation of the tone is represented by an

VALVULAR LESIONS OF THE LEFT HEART

The valvular lesions of the left heart are (congenital heart disease is not included.) In the diagnosis will be facilitated by the rule that if the lesion appears after birth, as a result of joint arteriosclerosis, we should think first of a left-sided congenital cardiac disease we think first of a

MITRAL INSUFFICIENCY

The essential fault in *mitral insufficiency* (or a systolic regurgitation of blood into the left atrium) depends upon the imperfect closure of the mitral valve to a systolic murmur. It is the most common of the valvular lesions. The regurgitation increases the pressure in the left atrium and dilates it (Law 2). The increased pressure is transmitted back through the entire pulmonary circulation. The pulmonary valves, however, are shut during systole and the right ventricle does not suffer from the increased pressure. The increased pulmonary pressure acting to the left ventricle during systole necessitates hypertrophy (Law 1, p. 382). Dilatation of the left atrium is an important element. The left ventricle contracts during its diastole than normally because the

hence it becomes primarily dilated (Law 2) because the pressure within it is increased during diastole. This dilatation leads in turn (Law 2) to a *secondary hypertrophy* of the left ventricle. The reason for the left ventricular dilatation is plainly compensatory; because, despite the fact that a part of its blood is regurgitated into the auricle, its increased capacity enables the arterial system to be completely filled.¹

In a well-compensated mitral insufficiency the systemic circulation is practically normal. The pulse is not at all small, as has often been stated, and the only striking disturbance which persists during compensation, even of a severe case of mitral insufficiency, is a more or less pronounced *dyspnea*, which ensues because the lungs are overfilled with blood. (See pp. 92 and 381.)

With this the series of compensatory changes in mitral insufficiency is complete. Clinically (Fig. 173), the lesion is recognized by a systolic murmur, generally heard with maximum intensity at the apex of the heart, but, under certain circumstances (see p. 333 et seq.), with its

Fig. 172.—Hydraulic diagram of mitral insufficiency: +, Increased pressure; +s, increased systolic pressure; +d, increased diastolic pressure; +ds, increased systolic and diastolic pressure in the heart chambers within which the signs appear. Hence, a heart chamber marked with +s hypertrophies primarily; one with +d dilates primarily; and one with +ds both dilates and hypertrophies primarily.

maximum at the base. This murmur may even overpower or obliterate the systolic mitral tone. Sometimes we can feel a thrill as well as hear a murmur. The primary dilatation of the left ventricle and left auricle can be demonstrated by percussion (frequently by palpation). Simple or pure hypertrophy of the right ventricle cannot ordinarily be appreciated by percussion (p. 242); but the increased pressure in the pulmonary circulation which produces this hypertrophy of the right ventricle is generally evident from an accentuation of the second pulmonic tone (p. 317), sometimes from the increased pulsation, or from the shock of the pulmonary valve closure, visible or palpable in the region of the pulmonary artery (p. 368). The diagnostic significance of the pulmonary second accentuation is, however, frequently overestimated. Not

¹ Theoretically, a very slight, practically negligible, deficit in the filling of the entire system of blood-vessels must necessarily ensue, because an extra amount of blood is required for the increased filling of the pulmonary circulation, of the left auricle, and of the left ventricle.

infrequently it fails to appear, for there are many cases where the compensatory power of the right ventricle is not sufficient to produce it, or cases of a mild degree of insufficiency, where the increased pressure is slight; and, finally, cases where, before the appearance of the mitral insufficiency, the pulmonic second was physiologically weaker than the aortic second. In contradistinction to the diastolic murmur of aortic insufficiency (see p. 397), it is that the murmur of mitral insufficiency is heard more when the patient is standing than when lying down, likely due to the action of gravity opposing the flow of blood. A faint mitral insufficiency murmur can frequently be heard in the recumbent posture.

The above-mentioned signs are ordinarily indicative of mitral insufficiency. Sooner or later, how-

Fig. 173.—Diagnostic diagram of mitral insufficiency. (The sign

compensation are bound to appear. They may appear in the following way: The right ventricle can no longer completely compensate; it dilates (paralytic dilatation, Law 4); as a result, the intensity of the second pulmonic disappears, and the left ventricle in turn receives less blood, and the pressure in the arteries and capillaries diminishes. This last danger is marked when, from the same cause, the left ventricle dilates. All the other appearances of disturbed compensation can be added to the lack of arterial filling until, after rest or cardiac tonics, compensation is again established and power then increases. The right ventricle again contracts completely and returns to its condition of pure compensation. But ordinarily during the course of reestablishing

tation of the right ventricle becomes anatomically fixed by the development of a secondary hypertrophy, *i. e.*, by the addition of layers of new muscular tissue (p. 386). This is permanent and can be demonstrated by percussion. (See p. 384 in reference to the completeness of the contraction of this permanently dilated right ventricle.) With the reestablishment of compensation the severe circulatory disturbances completely disappear.

The right ventricle may become dilated and hypertrophied in a similar way even without disturbance of compensation depending upon the conditions described upon p. 383.

The answer to the question as to whether or not the permanent dilatation of the right ventricle in mitral insufficiency has a compensatory significance depends upon whether or not we assume that the mechanism of the Fick's factor (p. 384) plays a part in improving the function.

(See p. 149 in regard to the characteristics of the pulse in mitral insufficiency; p. 353, in regard to the presence of a pulmonary pulse; p. 228, in regard to the depth of the lung borders from pulmonary stasis; p. 381, in regard to the character of the respiration; p. 318, in regard to the occasional disappearance of the mitral tone or both tones of the left heart; p. 337, in regard to the difference between a mitral and an aortic systolic murmur; p. 336, in regard to the occurrence of a prediastolic murmur, and p. 322, in regard to a splitting or doubling of the second tone.)

MITRAL STENOSIS

In mitral insufficiency the obstacle to the circulation is effective during systole; but in mitral stenosis, a comparatively frequent valvular lesion, the obstacle acts during diastole of the left ventricle. To understand

Fig. 174.—Hydraulic diagram of mitral stenosis. (See Fig. 172 for the explanation of the signs.)

what follows we should remember that the ventricular diastole can be subdivided into two intervals in relation to the auricle (Fig. 174). During the first part of the ventricular diastole the auricle is passive; the blood, under the influence of the pressure remaining from its course through the pulmonary circulation, flows into the left ventricle without the aid of the auricle. In mitral stenosis, however, an obstacle pre-

tole. There are no valves between the auricle and the lungs, and the distention of the auricle destroys any valvular closure, such as is assumed by physiologists to act through a ring-shaped narrowing of the orifices of the pulmonary veins; hence it is easy enough to understand that the contraction of the left auricle must drive back a part of the blood stagnating in the auricular chamber into the lungs and part through the narrowed mitral valve.¹ The increased resistance in the pulmonary circulation persists until the ventricular systole occurs, and can be overcome only by the hypertrophy (primary) of the right ventricle (Law 1). Thus, the hypertrophy of the right ventricle in mitral stenosis enables compensation to be effected by producing a continuous diastolic flow through the stenosed mitral valve. It presupposes an elastic tension of the pulmonary vessels, so that the systolic power of the right ventricle is transmitted through the lung into the left auricle. The effect upon the left auricle and the pulmonary vessels can be likened to the action of a wind hose. Despite its complexity, this supposition alone seems to explain that the systole of the right ventricle aids in producing compensation, although the obstacle is diastolic.² The conditions are much simpler in mitral insufficiency; for here, as a direct result of the regurgitation, both ventricles are working directly at variance, making it perfectly clear why the right ventricle must do more work.

There is no necessity for a dilatation of the hypertrophying right ventricle in mitral stenosis, any more than in mitral insufficiency, because, in either case, so long as the pulmonary semilunar valves close perfectly, there is no increase of right ventricular pressure except during systole (Law 1). Nevertheless, a dilatation may also occur in mitral stenosis, and then it is produced in the same fashion as in mitral insufficiency. (See p. 390.) In regard to its compensatory significance, see p. 384. Stenosis of the mitral valve furnishes no reason for any change in the left ventricle. In a well-compensated mitral stenosis the left ventricle evidently does not show concentric atrophy, as is sometimes contended, because our conception of good compensation is not compatible with the supposition, necessarily included in such a contention, that the diminished left ventricle forces decidedly less blood than normally into the systemic arteries.³

We not infrequently see at the autopsy table a case of mitral stenosis with a large right and a small left ventricle. The reason is either that the lesion could not be compensated, on account of the extreme degree of the obstruction (essential stasis⁴), or that the patient died during a disturbed compensation, in which the incomplete systole of the

¹ The fact that a considerable portion of the blood is driven backward instead of forward by the auricular contraction also explains the absence of dilatation of the left ventricle, in spite of the increase in the pulse volume of the left auricle.

² This passive elastic function, in which the propelling force is traced back to the right ventricle, is in reality a normal function of the left auricle and the pulmonary vessels, since during the first part of the ventricular diastole the blood flows into the left ventricle mainly on account of the excess of pressure which is left over from the lungs.

³ The deficit which the systemic circulation suffers in consequence of the collection of blood in the left auricle and in the lungs is of little importance to the left ventricle during the stage of compensation, because the vessels of the greater circulation possess a capacity for adapting themselves to varying degrees of fulness. Perhaps the deficit is cared for by an increase of the blood-mass. (See p. 382.)

⁴ The reader is referred to the author's paper: "Herzmittel und Vasomotoren-mittel" (Cardiac and Vasomotor Remedies), Cong. f. inn. Med. at Berlin, 1901.

p. 322 et seq.), and occasionally a presystolic or diastolic tone, due to an imperfectly opened mitral valve. (See p. 324 et seq.)

During quiet cardiac action sometimes the only auscultatory sign of mitral stenosis is a triple rhythm, the third tone of which is furnished by the presystolic tone. Besides, it is well to remember that mitral stenosis is more liable than any of the other valvular lesions to run its course without giving rise to a murmur. (See p. 330.)

In regard to the character of the pulse of mitral stenosis see p. 149; in regard to the character of the respiration see pp. 92 and 381; in regard to the presence of a pulmonary pulse see p. 353; in regard to the deep position of the lung borders on account of pulmonary rigidity see p. 227 et seq.

AORTIC INSUFFICIENCY

Aortic insufficiency—imperfect closure of the aortic valve (Figs. 176 and 177)—is, next to mitral insufficiency, the most common valvular lesion. Its mechanism is the one most readily comprehended by the

Fig. 176.—Hydraulic diagram of aortic insufficiency. (Compare Fig. 172 for explanation.)

beginner. The fault is that during diastole (Fig. 176) the blood rushes back into the left ventricle through the imperfectly closed semilunar valves, and so gives rise to the characteristic diastolic murmur (see below). Without compensation the mechanical effect upon the circulation would be that the aorta, deprived of part of its blood during diastole, could not fill the arteries and keep up the pressure. Compensation prevents such a result in the following way: The regurgitating blood enters the diastolic relaxed left ventricle. This chamber is at the same time receiving blood through the mitral valve. Its walls have, therefore, to endure an increased pressure during diastole, and hence become dilated (p. 382 et seq., Law 2). In virtue of its reserve power the left ventricle still contracts itself completely, and naturally sends an increased volume of blood into the aorta. But it cannot continually perform this extra work without hypertrophy (Law 2). As soon as hypertrophy takes place, the valvular lesion is compensated, and, for the time being, harmless. Then, at every systole, the aorta receives more blood than normally, and the loss through regurgitation is not significant. So

compensation may be repaired; and then, depending upon the individual peculiarities of the case, the right ventricle either regains its normal size, or else, if a relative mitral insufficiency (see p. 383 et seq.) persist on account of the permanently dilated (see p. 383) left ventricle, it may remain permanently hypertrophied, or both hypertrophied and dilated. Such a permanent dilatation of the right ventricle, supposing it contracted itself completely, would produce secondarily a further enlargement of the left auricle and ventricle (excessive compensation?). (See p. 384.)

The most important of the physical signs of this valvular lesion (Fig. 177) is a diastolic murmur audible at the aortic area and over the sternum. (See p. 332, 2.) The murmur is sometimes plainly transmitted into the carotids, and is usually more distinctly heard in the standing than in the recumbent posture, because gravity favors the regurgitation. A weak murmur of aortic insufficiency (contrasted with that of a mitral insufficiency, p. 390) is, therefore, oftentimes audible only while the patient is standing.¹ The second aortic sound may be absent; again, it may be unaffected if the aortic valves be not much diseased, or it may even be accentuated, in consequence of the increased systolic filling of the aorta; but, more frequently, on account of the damaged aortic valves, it is diminished or even disappears. In most cases of aortic insufficiency a systolic murmur can also be heard over the aorta. According to one hypothesis, this systolic murmur depends upon a roughness at the aortic valves, due to endocarditis or atheroma, which affects the blood-current during systole, although there is no actual stenosis (p. 328, 2). According to another hypothesis, the systolic murmur results from the diastolic regurgitating stream clashing with the systolic stream. According to a third hypothesis, it is the result of the increased rapidity of expulsion of the blood from the more powerful systole (p. 327). However this may be, it is well to be cautious in making a diagnosis of aortic stenosis from the presence of a systolic murmur heard over the aorta in a case of aortic insufficiency unless there are other signs of stenosis. An especially rough or musical murmur speaks with some probability for the existence of an aortic stenosis; but the deciding point is the character of the pulse. If there be an actual aortic stenosis,—that is, a mechanical narrowing,—the pulse will possess, more or less plainly, the characteristics of the *pulsus tardus*. (See p. 115 et seq., p. 144.) See p. 340 in regard to the presence of a doubled maximum diastolic and systolic murmur, i. e., one heard very plainly both over the aorta and at the apex. A complicating mitral insufficiency or stenosis is often wrongly diagnosed from such signs.

Austin Flint² described in aortic insufficiency a presystolic murmur audible over the auscultation area of the mitral valve. He explained it in this way: The regurgitating stream from the aorta spreads out the curtain of the mitral valve just as the presystolic stream from the left auricle is passing through this valve into the left ventricle. Hence the mitral curtain cannot be completely opened, and a sort of functional mitral stenosis results. This produces the presystolic murmur. This explanation does not seem to the author sufficiently proved by the postmortem findings; nevertheless, it deserves diagnostic attention. A certain differentiation of this condition from the combination of an aortic insufficiency

¹ [A very faint murmur of aortic insufficiency can sometimes be appreciated by the ear against the chest when it is not audible through the stethoscope.—Ed.]

² [Flint's murmur, first described in *Manual of Auscultation and Percussion*, Austin Flint, third ed., 1883, p. 231.—Ed.]

percussion. (See p. 242.) Sooner or later, however, disturbances in compensation generally occur, and a secondary dilatation of the left ventricle is added to the hypertrophy (Law 4). This dilatation either disappears

Fig. 178.—Hydraulic diagram of aortic stenosis. (Compare Fig. 172 for explanation.)

when compensation is restored, or may persist as an anatomic change. (See p. 384 et seq.) Such a permanent dilatation (p. 384) sometimes develops without being preceded by a real disturbance in compensation.

Fig. 179.—Diagnostic plan of aortic stenosis. (For explanation of the signs see p. 388.)

(See p. 384 et seq. in regard to the completeness or incompleteness of contraction of such a permanently, secondarily dilated and hypertrophied ventricle.) It need scarcely be mentioned that, through disturb-

ances in the compensation, an aortic stenosis effect upon the pulmonary circulation and seq.) as aortic insufficiency.

The physical signs of aortic stenosis are palpation reveals a systolic murmur, audible at the second right intercostal space, transmitted to the neck, and sometimes audible over the heart. The murmur is also palpable at times, and may be very loud. It is so constantly loud that the demonstration of aortic stenosis argues in favor of aortic stenosis and against aortic insufficiency as a matter of fact, the conditions for murmur (large volume of the stream) aortic stenosis than in almost any other valvular disease. It possesses two maximum points (over the aorta and at the base of the heart). This may produce the erroneous impression of mitral insufficiency. The most essential sign is *pulsus tardus*, the presence and peculiarity of which is well explained. (See pp. 115 et seq., and 144.) Very rarely *pulsus tardus* exists, and the only abnormality is *pulsus celer*. (See p. 144.) This latter peculiarity may depend upon causes that it is of no diagnostic value. The pulse is to-day a requisite for the positive demonstration of aortic stenosis. The tension of this deliberate and small pulse of compensation is not necessarily low. Often the pulse is small, but also less frequent than normal. In the early stage of aortic stenosis it is an important element of complete compensation, and is therefore of great significance. Despite the hypertrophy of the left ventricle the impulse is said to be frequently weakened; but this is not always the case. Where such a weakened apex impulse is found, Skoda's theory that it is due to a loss of force by the slowness of cardiac emptying will not satisfy. We must know that the apex impulse coincides with the heart-beat. Hence we must acknowledge that the heart impulse has been finally disproved. The theory seems more plausible. He claims that the more rounded left ventricle, and that it is more rounded apex to reach between the ribs, and is therefore more easily heard. But, as a rule, the cardiac apex is also obscured by aortic insufficiency, and yet in this latter lesion the apex impulse is quite pronounced. The author considers the weakening of the apex-beat and aortic insufficiency as disproved. Besides, many cases of aortic stenosis show a slowly heaving apex impulse which has been described on p. 359.

There is nothing characteristic about the heart-beat in aortic stenosis. Ordinarily, they persist. Under some circumstances the tones over the entire left heart make the diagnosis of aortic insufficiency complicates the aortic stenosis. In aortic stenosis the shape of the cardiac dulness as on percussion is normal; hence the probability of confusion between the murmur of an aortic stenosis and an accident

or roughness of the aortic intima. The pulse should distinguish the two conditions. Other kinds of accidental murmurs (anemia, fever) are less difficult to diagnose, because their maximum is not usually over the aorta. The author has already emphasized (p. 397) the frequent error of diagnosing a complicating aortic stenosis because a systolic murmur is heard over the aorta in addition to the diastolic murmur in aortic insufficiency. The presence or absence of the *pulsus tardus* should be distinctive in this case as well. To distinguish the murmur of aortic stenosis from that of mitral insufficiency we should carefully locate its maximum intensity and notice the characteristic, although slight, difference of phase (p. 336 et seq.).

VALVULAR LESIONS OF THE RIGHT HEART

In the diagnosis of valvular lesions of the right side of the heart it is important to remember that they are most frequently congenital lesions, and that they rarely originate during extra-uterine life; this is exactly the reverse of left-sided lesions. Nevertheless, acquired right-sided valvular lesions are not quite so rare as is sometimes claimed. When they do originate after birth, they are most frequently complications of coexistent left-sided lesions.

TRICUSPID INSUFFICIENCY (Figs. 180 AND 181)

As a relative insufficiency complicating left-sided valvular lesions, this lesion occurs quite frequently; but as a true anatomic valvular change, it is rare except in congenital heart disease. The weak right auricle is all that exists behind the tricuspid value to compensate the

Fig. 180.—Hydraulic diagram of tricuspid insufficiency. (For explanation see Fig. 172.)

disturbance. Its compensatory power is naturally limited, so that the disturbance to the circulation is more serious than in mitral insufficiency. The first result of a tricuspid insufficiency (see Fig. 180) is a dilatation of the right auricle, because the regurgitating blood distends this chamber during its diastole (p. 382, Law 2). The dilated auricle, having more blood to propel, necessarily hypertrophies (Law 2). It

ciency unless the former be a relative one, and, with the aid of cardiac tonics, capable of retrogression.

In this lesion a dilatation of the right auricle and right ventricle can be made out by percussion and sometimes by palpation. (See Figs. 181 and 142.) Auscultation discloses a systolic murmur over the tricuspid area (p. 333). This murmur can be differentiated from the murmurs of pulmonary and aortic stenosis by a slight difference in phase (p. 337). During compensation the second pulmonic may retain its normal strength; during disturbance of compensation it may be diminished. The heart tones over the right ventricle may remain normal if the insufficiency be slight, or be weakened if the insufficiency be marked, just as in mitral insufficiency. (See p. 318.) Much the most important and suggestive symptom of tricuspid insufficiency is the coincident ventricular systolic venous pulse (p. 196 et seq.) visible in the jugular veins, often visible as a liver pulse, and visible sometimes even in the small cutaneous veins of the body. The positive venous pulse in the jugular veins is, under some circumstances, accompanied by a systolic tone over the vein, depending upon the systolic tension of the vein-wall and of the valve at the bulb (p. 349). The venous pulse is present both during effective compensation and during disturbed compensation. The ventricular systolic pulse may originate in the absence of tricuspid insufficiency from a paralysis of the right auricle. Concerning a palpable pulsation of the right auricle in tricuspid insufficiency see p. 367. The arterial pulse remains normal during perfect compensation; but such compensation is possible only with slight degrees of tricuspid insufficiency. During disturbed compensation it very quickly assumes a dangerous diminution of volume and tension.

TRICUSPID STENOSIS

This valvular lesion, fortunately, is very rare, both in the congenital and the acquired forms (Figs. 182 and 183). Like tricuspid insuffi-

Fig. 182.—Hydraulic diagram of tricuspid stenosis. (For explanation see Fig. 172.)

ciency, it can be compensated with difficulty, and then generally for a short time only. (See Fig. 182.) Compensation takes place in this way: The right auricle, in consequence of the obstruction to the entrance

the other tones, may retain their normal character during compensation. Concerning the occurrence of an apparent or real accentuation of the first tone at the tricuspid valve in tricuspid stenosis, analogous to the accentuation of the first tone in mitral stenosis, see p. 318 et seq. It is readily understood that the auricular venous pulse is especially marked in tricuspid stenosis. The presence of a (presystolic) auricular liver pulse is credited with diagnostic importance by Mackenzie, but he is contradicted by Volhard.

Under some circumstances a presystolic or diastolic tricuspid tone, analogous to the presystolic or diastolic mitral tone, may be of some diagnostic service (p. 323 et seq.).

PULMONARY INSUFFICIENCY¹

Pulmonary insufficiency, an inability of the pulmonary semilunar valves to close perfectly, is a rare valvular lesion and usually congenital (Figs. 185 and 186). Its effect upon the lesser circulation is

Fig. 184.—Hydraulic diagram of pulmonary insufficiency. (For explanation see Fig. 172.)

analogous to the effect of an aortic insufficiency upon the greater. Compensation (see Fig. 184) will be understood by referring to that lesion. In this lesion it depends upon dilatation and hypertrophy of the right ventricle.

The diagnostic signs consist essentially in a diastolic murmur heard over the pulmonic area (Fig. 185), and transmitted downward (p. 333), and in the demonstrable dilatation of the right ventricle. The diastolic murmur, unlike that of aortic insufficiency, is not transmitted to the neck vessels. The tones are generally normal, just as in aortic insufficiency. The *pulsus celer* belongs to the pulmonary circulation, and, so, naturally escapes notice, or at most betrays itself only by an exceptional pulsation of the pulmonary area, provided the latter be not covered by lung tissue (analogous to the increased aortic pulsation in aortic insufficiency, p. 396 et seq.). The lack of a *pulsus celer* in the peripheral arteries aids in distinguishing pulmonary from aortic insufficiency.

left, ventricle; obliteration of the aorta at the entrance of life is preserved by the formation of a collateral circuit (the lower part of the aorta). It need not be said in these conditions, whether they appear isolated or as combined defects. Only a few hints can be given in the present

Much stress is ordinarily laid upon the exception which appears so frequently in congenital heart disease to attribute to the admixture of venous with arterial circulation. The conditions are, however, especially favorable in right-sided valvular lesions, without supposing venous blood, because, on the one hand, compensation is soon disturbed (*e. g.*, tricuspid lesions), and because, on the other, even in pulmonic lesions, as soon as there is stenosis, the stasis must be concentrated in a most direct systemic veins, whereas in left-sided valvular lesions there is no such reservoir for the stagnating blood. Therefore, in congenital heart disease, to make a diagnosis of an abnormal communication between arterial and venous blood simply from marked cyanosis, is to deny the possibility of such admixture cyanosis, without any special considerations. They are supported with some communications between the ventricles and between the ventricles and the aorta, which are found at autopsies without any signs during life of admixture cyanosis. It is not surprising that this lack of admixture cyanosis (despite the fact that the two abnormally communicate) is so common, so that no blood need be sent from the right ventricle to the left, every abnormal communication of the cardiac cavities is accompanied by cyanosis, but it is probable that under certain conditions admixture cyanosis may be absent.

A mere defect in the septum between the auricles causes no admixture cyanosis; yet it is perfectly possible that an effect may result if, at the same time, a right-sided valvular lesion exists. With tricuspid insufficiency, for example, and an open foramen ovale, the systole may force the venous blood out of the right auricle into the left, but also, in consequence of its increased pressure, the blood may flow through the tricuspid stenosis, during ventricular diastole, the blood may partly flow in the direction of least resistance through the foramen ovale into the left auricle and ventricle. Just so it is conceivable that, during systole the blood from the right ventricle is forced through a patent ventricular septum, the presumption being that the septum has become so strongly hypertrophied that it overbalances the resistance of the tricuspid valve.

The plainest and, perhaps, also most frequent example of admixture cyanosis is the "straddling" of the aorta, *i. e.*, its origin from both ventricles, due to a defect in the ventricular septum. Here, of course, the blood is mixed. We observe this appearance in congenital heart disease.

Patency of the ductus Botalli, on the contrary, is not accompanied by admixture cyanosis, because the aortic pressure, if not always higher than that of the pulmonary artery, so that the blood flows from the aorta into the pulmonary artery, but not in the reverse direction. The blood must flow into the aorta if the ductus Botalli is patent, because the aorta must obtain its blood from the opening in the septum between the ventricles.

In congenital valvular lesions, therefore, it is reasonable to suspect admixture cyanosis, and to be fairly certain of its existence when the cyanosis is very pronounced while the veins are very little dilated (stasis).

In any given case, however, the cause of the admixture cyanosis must be determined. In tricuspid lesions we should naturally expect admixture cyanosis; whereas in pulmonary stenosis a patent ventricular septum, or a straddling aorta, would be more probable. Under these conditions a murmur at the cardiac apex may be a positive sign of admixture cyanosis. This sign is, however, of very little practical value, as just where a patent ventricular septum is to be taken, aortic murmur is frequently very plainly audible over the aorta, and aortic murmurs are heard from the entire right ventricle (p. 333, 7.)

It is difficult to diagnosticate patency of the ductus Botalli. We should remember that this anomaly very often accompanies congenital pulmonary stenosis. Zinn and Hermann Müller¹ have called attention to a band-like dulness reaching upward and to the left of the upper part of the sternum. They attribute this to the dilatation of the overburdened pulmonary arteries which results from the aortic pressure. An accentuation of the second pulmonic has been repeatedly stated to be a result of a patent ductus Botalli, because with this abnormality the pulmonary arteries are affected by the aortic pressure. Müller attributes diagnostic significance to the systolic and diastolic murmurs which appear over the great vessels, and states that they sometimes merge into a practically continuous murmur. The systolic murmur depends upon the systolic passage of blood from the aorta through the narrow ductus Botalli into the pulmonary aorta; the diastolic murmur, upon the diastolic continuation of this current. The congenital obliteration of the aorta at the place of origin of the ductus Botalli is, on the contrary, very easy to diagnose, whether it be associated with congenital valvular lesions or isolated. The collateral circulation, by which the blood flows from the peripheral arteries of the upper part of the body (subclavian, etc.) to the lower part of the aorta, becomes visible under the skin and makes the diagnosis clear. Such an obliteration may exist without any disturbances of the circulation.

There are many questions in the pathology and diagnosis of congenital heart lesions which still lack solution.

THE DIAGNOSIS OF DEFECTS OF THE VENTRICULAR SEPTUM

The work of H. Roger,² and more especially that of H. Müller,³ upon the clinical and postmortem findings in cases of defects of the ventricular septum show that it is possible to diagnose this lesion from its clinical picture. One of the most important elements of their work was to demonstrate that defects of the ventricular septum occur alone and uncomplicated much more frequently than has been supposed, and thus correspond to a clear and simple clinical picture. Litten⁴ was responsible for the current belief that these defects are usually accompanied by other anomalies, such as defects of the auricular septum, pulmonary stenosis, patent ductus arteriosus, etc. Such a belief thoroughly discouraged attempts to diagnose the condition and made the interpretation of the systolic murmur accompanying a defect of the ventricular septum very difficult. In France, Roger's work long ago led to the acceptance of a clinical picture of this anomaly, and there the disease is known as *la maladie de Roger*. Müller's work, with the abundant material presented by him, deserves the credit for calling attention of the German profession to the condition under discussion. Roger states the characteristics of the disease in the following words, quoted almost verbally in Müller's paper.

1. Defective ventricular septum is a congenital anomaly of the heart which is quite compatible with longevity; it sometimes occurs without an accompanying pulmonary stenosis, does not in itself lead to cyanosis, and it can be diagnosed during the patient's life.

2. The diagnosis is based chiefly upon the auscultatory findings. The characteristic sign is a loud, prolonged, rushing or purring murmur (*bruissement*), which is quite unique in character. This murmur begins during systole and continues in such a manner as to obscure completely the normal "tic tac" of the heart; it is most intense not at the apex, as in mitral disease, nor at the base to the right of the sternum, as in aortic stenosis, nor to the left of the sternum, as in pulmonary stenosis, but in the upper third of the precordia; it is heard best in the median line corresponding to the median position of the septum itself, and gradually diminishes in intensity toward the lateral regions of the precordia; it is sharply localized, is not transmitted into the vessels, and is frequently accompanied by a well-marked thrill. A murmur with the above characteristics forms, according to Roger, a pathognomonic sign of a defect of the ventricular septum. This writer does not mention the size of the heart or the character of the heart sounds. Müller likewise strongly emphasizes the auscultatory phenomena for the diagnosis of the condition, and lays stress upon the loudness of the murmur, which quality he ascribes

¹ Correspondenzbl. f. Schweizer Aerzte, 1889, p. 449.

² Bull. de l'acad. de med., 1879, No. 42, translated by Löffler in Med.-Chir. Centralblatt, Vienna, 1881, xvi, and Revue de méd., Paris, 1879, p. 681.

to its production by a stream of fluid under opening during systole. Frequently the murmur hardly exceeded in intensity by the sounds heard in aortic stenosis, thus approaching most in character occasionally it may be heard a few centimeters from the heart, but it does not possess any real musical tone. Müller, holding the ear a slight distance from the stethoscope, accompanying the murmur. As has been noted, it is well transmitted into the vessels, but it is less well as behind, especially in the left intercostal space. The second pulmonic tone was generally neither accentuated, in one of Müller's cases was accentuated in the pulmonary artery. In none of Müller's cases was the reason being that the cusps of the mitral valve were defective in the ventricular septum in this position of pressure in the two ventricles is not a sign of any considerable stream of blood from the right to the left. Müller describes a diastolic murmur in addition to the systolic murmur in this case an open ductus arteriosus complicating the case. Special stress upon the site of the murmur, found beneath the third rib at the left sternal angle, the projection of the defect in the septal wall, which would intersect the surface of the chest. In Müller's cases it was distinctly heard in the second left interspace, suggesting pulmonary stenosis for the lesion. At the apex of the heart the murmur was usually less intense, fainter, at the right of the sternum. As Rogers has shown, it is never most intense at the site of auscultation. A well-marked thrill was present almost always, but the intensity of the murmur; occasionally a thrill was present at the right sternal margin; and in one case (with a large heart) a thrill could be appreciated over that area. Rogers describes very carefully the changes in the size of the heart in the defects of the ventricular septum. In early cases the heart is of normal size; later the right ventricle is hypertrophied and dilated. In the author's cases the changes in the heart are easily explained by the laws of compensation in cases in which the heart is not found to be normal. The character of the defect is such as to result in hydrodynamic effects upon the blood current.

The changes in size may be explained as follows: The heart is compelled to work to a certain degree against each other. The high pressure in the left ventricle compels the right ventricle to dilate and thus it hypertrophies. Because of the dilatation, especially as it receives an extra amount of blood (Compare the circumstances in mitral insufficiency) everything said about the conduct of the heart in mitral insufficiency applies in this connection, and the analogy of the left ventricle. If the right ventricle becomes dilated, which occurs in marked defects of the septum, the flow of blood to the left heart by way of the pulmonary artery on the left side likewise dilates, the left auricle as well as the left ventricle, produced, as in mitral insufficiency, the action of the heart is to push the blood forward and back through the mitral orifice. In insufficiency, the left heart is overfilled during diastole, does a large amount of work, becomes hypertrophied.

This presentation of the compensation in defects of the septum leads, at least, to conclude that the differential diagnosis between aortic stenosis and mitral insufficiency, especially when one of the lesions is not without difficulty; indeed, the truth of this conclusion. The difficulty in the diagnosis of mitral insufficiency, as we have seen (p. 333) is that the site of maximum intensity of the murmur of mitral insufficiency on the surface of the heart be abnormally exposed. It may not be accentuated in mitral insufficiency, as just learned, it may be accentuated when the

Müller observed two cases with such an accentuation. A dilatation of the artery in certain cases furnishes further difficulties in diagnosis, for then the lesion for an open ductus arteriosus is quite possible, as an experience very well shows. The presence of a characteristic dulness to the left of the heart, caused by the dilated artery, led Müller to diagnose a patent ductus arteriosus. The autopsy, however, showed that the lesion consisted of a defect of the ventricular septum, accompanied only by a dilatation of the pulmonary artery. The point of such dilatation of the pulmonary artery is to be sought in all probability in the decreased energy of the right ventricle. The point of differentiation between a defect of the ventricular septum and a patent ductus arteriosus may be considered to be the presence of a systolic and a diastolic murmur in the latter case. (See p. 408.) However, in spite of these undisputed difficulties, the diagnosis of defects of the ventricular septum seems often to be quite easy, and especially is this the case when marked changes have taken place in the size of the heart. The latter point is valuable because the absence of increase in the size of the heart is probably never to be noted in a condition accompanied by such well-marked murmurs. In addition, the intensity of the murmurs is of diagnostic significance. Finally, both Roger and Müller have remarked the absence of cyanosis in these cases, except when they are accompanied by marked pulmonary changes, such as catarrhal pneumonia, emphysema, and miliary tuberculosis, observed once.

ANEURYSM OF THE AORTA

Aneurysms are most frequently situated upon the ascending aorta or upon the arch of the aorta. When an aneurysm reaches a certain size, we can detect a swelling in the upper intercostal spaces to the right of the sternum, and appreciate it by palpation as well. Small aneurysms may not exhibit any prominence, and

Large aneurysm of ascending and transverse arch of aorta (New York City Hospital).

Diagnosis can only be appreciated by palpation. Valuable information may be obtained by palpation with the stethoscope. (See Auscultatory Palpation, p. 408.) When the aneurysm reaches the surface, percussion will show a marked dulness continuous with the cardiac dulness, and, being a superficial dulness, is easily brought out by very light percussion. If a layer of lung remain in front of the aneurysm, the dulness may be either entirely absent or there may be only a deep dulness, demonstrable by strong percussion. Even here, the pulsation may be transmitted through the overlying layer of lung to the surface. Auscultation very frequently reveals a systolic murmur, which may sometimes be appreciated by palpation. The entrance of the blood into the aneurysmal sac produces

this murmur as a result of a change of lumen in the blood-path. (See Fig. 103, III, and p. 328 et seq.) This murmur, like that of aortic stenosis, is transmitted most distinctly in the direction of the aortic current, *i. e.*, to the neck vessels. Diastolic murmurs are, however, sometimes due to aneurysms. The proof that such a murmur arises from the regurgitation of blood into the sac, which is stretched during diastole and not from a complicating aortic insufficiency, is furnished by the existence of similar murmurs over aneurysms of the abdominal aorta.¹ Under some circumstances a diastolic murmur may be one of the earliest signs of an aortic aneurysm, and may readily lead to a confusion with aortic insufficiency unless the aneurysm is evident to inspection, palpation, and percussion. Frequently, however, the diastolic murmur over an aortic aneurysm depends upon the coexistence of an aortic insufficiency. For the sac, continually increasing in size, gradually produces a dilatation of the aortic orifice, and so a relative insufficiency, or else the endarteritis, which is always present in an aneurysmal aorta, attacks the valves as well. Unless an aortic aneurysm be combined with a valvular lesion, the heart need not be hypertrophied nor dilated, because an aneurysmal dilatation of the aorta by

Fig. 190.—Aneurysm of the descending arch of the aorta (Dr. Cutler, Massachusetts General Hospital).

itself offers no considerable obstacle to the circulation. Large aneurysms, on the contrary, generally crowd the heart somewhat to the left, so that the apex-beat lies further outside than normally. To determine the exact seat of the aneurysm in relation to the origin of the innominate and of the left carotid and left subclavian arteries, we should accurately compare the exact time and strength of the carotid and radial pulses on the two sides, both by palpating and by the use of the sphygmograph. The aneurysmal dilatation frequently delays the pulse in those arteries which arise from the aorta beyond the aneurysm, because a sort of air-vessel action retards the pulse-wave. In other cases the delay is due to the fact that some of the arteries arise from the sac itself and are narrowed at their origin. The pulse in such an artery may then be also abnormally small and delayed by crest-retardation. (See p. 151 et seq.) In many cases certain accompanying signs which are to be attributed to the pressure of the aneurysm are important in confirming the diagnosis: pressure upon the trachea, with dyspnea; upon the esophagus, with difficulty in swallowing; upon one of the bronchi (generally the left), with a diminished respiratory

cause a pericardial friction rub, because the exuded fibrin in addition to the fluid (p. 34). *exudative pericarditis* is, however, a character which is increased upward; and which ordinarily as with its base below (p. 248 et seq.). The rib is decidedly blunted. The width of this is sitting or erect posture (p. 248 et seq.).

(p. 360), and the heart tones are also changed in the outer portions, on account of the increased cases the apex-beat lies within the borders of the heart (p. 360 et seq.), and frequently there is a visible cordia (p. 34). Beyond these features the illustrations illustrate the entire clinical picture of exudative pericarditis. A border of deep cardiac dulness is often found and the heart is apparently laid bare by the fluid, causing only a very large superficial dulness in regard to the diagnosis of pericardial synechia adhesions. These have recently assumed a new name for cardiolysis.)

GRAPHIC EXPRESSIONS FOR THE DIAGNOSIS OF DISEASES IN PULMONARY C

In the sections upon Percussion, Auscultation of the lungs we have described and explained the significance of the individual physical signs of pleural affections, and so now we need only to explain our method of combining these signs in a graphic picture in any given case. The arrangements of signs in pulmonary and pleural affections are more numerous than in cardiac affections, that it is only in the former as completely as the latter have been treated in the preceding pages. The author has, therefore, in this section, for the sake of simplicity and brevity we have only to describe the lung conditions. These have been arranged at Bern, both practical and comprehensive.

The rules for such graphic expression are as follows: We represent the respiratory murmur of the lung by a small right angle, and place the sign of the lung spot upon a chest diagram. This sign is modified in various ways, according to the modification of quality of the murmur. The vertical limb of the angle represents the horizontal, the expiratory murmur; the thickness, its duration; the thickness, its intensity. A straight line signifies normal vesicular breathing; a wavy line, rough breathing; a toothed line, rough vesicular breathing; a line on the limb signifies mixed breath

EXAMINATION OF THE STOMACH CONTENTS

Under the examination of the stomach we determine the estimation of its size and position, and what can be determined by palpation (tenderness, deformity, but more particularly the methods of testing contents). Purely physical methods of examination furnish us with few points. Therefore, the bulk of the following is devoted to the functional examination of the stomach, and to the examination of its secretion relations. Under the examination of the abdominal viscera the author has already given a physical diagnosis. (See pp. 257 et seq., 277 et seq.) He has intentionally postponed until now any mention of the physical methods of examining the stomach, which methods reveal but isolated symptoms which are in connection with others.

Many of the cases require the employment of the stomach tube, although its use is attended with certain disadvantages, even with injuries, to the patient. Still, quite a number of diagnostic points may be obtained without it; it is advisable to employ the other methods of

THE SIZE AND POSITION OF THE STOMACH

In this connection some of the results of Witzel,¹ as well as those of Röntgen-ray examination, merit mention.

His¹ found, as Luschka had before him, that the stomach does not hang down, but is contracted, so that its walls appear thickened. Luschka, however, considered the pylorus as points of fixation; but Braun showed (and His has confirmed) that not the pylorus but the second part of the duodenum (the *duodenojejunal junction*) is the point of fixation, and that, accordingly, as clinical experience with the pylorus can undergo marked changes in position. His states further that, contrary to the older notion, the stomach lies in the median line; when the organ is filled it rises upward and the greater curvature looks somewhat toward the spinal column; whereas, when the stomach is empty the greater curvature looks somewhat downward. The lesser curvature runs downward and to the right until the pylorus is reached. At moderate filling, on the contrary, the *pars pylorica* rises from the deepest part of the stomach (His), so that it is the *fundus* which is the portion. This formerly much-disputed question, which of great significance, has been answered in the same way as above. The female stomach is, according to His, more contracted than that of males. The corset stomach of laced women is characterized by a dependent loop with a decided lateral concavity.

Rieder,² Grödel,³ and Holzknecht⁴ have recently studied the size of the normal stomach with the x-rays after filling.

¹ Arch. f. Anat. u. Physiol., Anat. Section 1, 1903.

² Fortschritte auf dem Gebiete der Röntgenstrahlen, 1904, 35, and *ibid.*, 1906, 3.

⁴ Berl. klin. Woch., 1906, 5.

paste. Both Rieder and Grödel decided that in the erect posture the normal full stomach is fish-hook or siphon shaped. The left half of the filled stomach assumes an almost vertical position, reaching to the level of the umbilicus or below it, and thence turning up sharply to the pylorus (Fig. 199). Grödel found that the upward bend of the stomach disappeared in the recumbent posture (Fig. 199, dotted line). The picture thus approaches Luschka's anatomic representation (see Fig. 120) more closely in recumbency on account of the alteration in the direction of the force of gravity. Grödel is, however, of the opinion that even in this position there is a hook-shaped bend of the stomach, with the difference that the site of the curve is shifted toward the spinal column under the influence of gravity. Only exceptionally (in but 1 of 92 cases and that in a cripple) did Grödel find the pylorus to be the lowermost part of the stomach, although Holzkecht found this to be the rule. Such a state of affairs is, however, unlikely, for physiologic reasons. According to Symmonds, the hook-shaped stomach is found even in the first year of life. Not uncommonly irregularities in the shape of the stomach occur, especially a left-sided

Fig. 199.—Form and position of the normal stomach of a sixteen-year-old youth in the erect (continuous line) and recumbent (dotted line) postures. The part above the transverse line in the first picture is filled with air above the bismuth paste used to distend the stomach. It is called the stomach bladder (bubble) (F. M. Grödel).

hollowing of the vertical part. This is especially frequent in women as a result of tight lacing. The author mentions it because he has known the Röntgen-ray picture of such an abnormal form to lead to the incorrect diagnosis of hour-glass stomach or even of gastric tumor. Grödel's projection pictures do not correspond to the results of inflation and percussion (see p. 424) because, as he was able to show, inflation with air displaces the stomach upward in an abnormal manner, whereas filling the organ with bismuth stretches it downward. The results of percussing the boundaries of the stomach after filling the organ with water or food are, on the other hand, quite comparable to the Röntgen-ray pictures.

METHODS OF EXAMINATION WITHOUT EMPLOYING THE STOMACH-TUBE

The subjective symptoms in the diagnosis of stomach disorders play an important part, *i. e.*, the complaints, the kind of pain or vomiting, and the time when they occur, the character of the stools, etc., in short, the history in the broadest sense of the word. But all this belongs rather to special pathology.

For the objective examination, which chiefly concerns us, the author refers to the sections upon Inspection, Palpation, and Percussion of the Abdomen; but a few special points must be taken up here.

THE DETERMINATION OF THE SIZE, THE STOMACH WITHOUT THE USE CALLED SPLASHING

It is difficult to estimate the size of the stomach (p. 257), but, if the abdominal walls be lax, the outlines of the stomach, the greater an curvature as well. Palpation will sometimes palpate the tense stomach from the less tense intestine, but examination affords no definite result, as is from the stomach either with gas or fluid. The method is by giving the patient a teaspoonful of soda water immediately afterward the same amount of tartaric acid in a half-glassful of water. The alkaline solution is swallowed first, because the acid solution irritates the membrane be sensitive, and especially if a gas is added. An admixture of the two solutions produces carbon dioxide in the stomach so that its outlines can be determined by palpation, and percussion. If this test is hardly necessary. The experiment is, however, for the stomach may rapidly expel the gas. Again, a large dilated stomach may contain a great amount of more gas, and so we should have a second and larger dose of effervescing powder. Do not use too great an amount at first, because it may cause too much and cause pain. Inflating the stomach with an ordinary Davidson syringe.—[Ed.] is free from danger, and the amount of air can easily be controlled. It gives an incorrect picture because it overestimates the size, whereas the ordinary conditions of filling are more correct.

A reasonably accurate estimate of the size of the stomach can be reached in some cases by noting the change in the position of the stomach when the patient, while erect, swallows water. The stomach, to commence with the fasting stomach, will be entirely covered by intestine. After one or two glasses of water have been swallowed, the fundus will be palpable in the upper part, and light percussion will bring out a well-defined, bell-shaped dulness in the region of the greater curvature. It is perfectly easy to see that this dulness is due to the filling within the stomach, for if the patient swallows a small amount of the dull area will be increased upward and outward. If the stomach is of normal resistance (Fig. 200, b); but with a marked dilatation of the stomach, the weight of the stomach on the greater curvature (Fig. 200, c). The same result can be obtained by the stomach as x-ray examination shows a much greater filling. (See Fig. 199, p. 425) This method is less valuable than inflation with gas; besides, it is sometimes distressing to the patient, especially if carbonic acid water is employed.

The dislocation of the spleen in association with the stomach should always be borne in mind. The spleen is displaced downward by means of the gastrosplenic ligament, and is readily palpated.

unless they are elicited when the morning before breakfast, or more meal. If heard or felt under such insufficiency of the stomach, is dilatation of the stomach. Again an area larger than the normal (enlarged).

A very decided splashing sound over the stomach area suggests obtained within the time limits might call this "superficial splash" elicited by vigorous blows. That the stomach-walls are relaxed may not be associated with gas pathologically dilated stomach, any decided signs of atony, i. e., splashing, especially when the pylorus. A pathologic dilatation a superficial splashing, and condition superficial splashing (i. e., atony) and should be distinguished from going explanation of the significance be misconstrued, as it has been make a diagnosis of motor insufficiency demonstration of a superficial splash sufficiency and atony as identical merely a diminished tension. Multiplied by any other symptoms the length of time that the food any way prolonged by mere atony significant, not as a name of a clinical condition of the stomach, with of the gastric function may, vary. So far as the significance of "superficial splashing" should be noted that even relaxation of "superficial splashing," because equals the sum of the pressure of musculature, and because a suction action the less the tension of the stomach dent reasons "superficial splashing" the stomach (gastroptosis), quite of this position with gastric atony atony of the gastric muscularis is passive tension of the gastric wall despite the atony, the full stomach any "superficial splashing."

Sometimes a splashing may occur when it really proceeds from the small as in some cases of diarrhea. The demonstration of a similar splashing all will usually prevent any confusion small intestines and yet be perfect

enics and hypochondriacs sometimes consult their physicians a splashing sound which they produce themselves in the on by contracting and retracting their abdominal walls. may be a true splashing, but it is important only when it the conditions mentioned above. It may be produced when is quite normal and nearly empty by an alternate separating together of the stomach or the intestinal walls.

ON OF THE GASTRIC FUNCTIONS WITHOUT THE USE OF THE STOMACH-TUBE

tions of the stomach are: (1) Digestive, (2) receptive, and c. In the first place, it chemically alters proteins and carbohydrates thereby facilitates and aids in their resorption. In the e, it acts as a well-equipped reservoir, and at the proper s properly prepared food for the intestines to digest completely to assimilate. With this assistance it is possible to ingest a few definite periods, meal-times, and during the intervals ourselves to other interests. In the third place, it protects es from the injurious action of the noxious micro-organisms in the food. Hence we must study not only the chemistry digestion and the power of absorption of the gastric walls, ermine its motility and its germicidal function.

EXAMINATION OF THE VOMITUS

able information about the chemistry of digestion may be m carefully examining the vomitus. Even a macroscopic will enable us to draw valuable conclusions, especially in e digestion of meat, if the vomiting occur during the time digestion ought to be pretty well advanced physiologically. bits of unchanged meat or albumin in the material vom- three hours after eating, we are justified in assuming some of protein digestion. The changes of other kinds of food ach are less characteristic. Bread, however, should be in one to two hours after ingestion to a uniform mass of consistence, which settles as a granular layer at the bottom omitus is allowed to stand. If the vomitus at this interval mbs of unaltered bread, perhaps covered with mucus, we are ified in assuming disturbed protein digestion, depending on a deficient secretion of hydrochloric acid. We may also ute iodine solution to determine the degree of amyloid diges- will be described later in connection with the Test-breakfast eq.). But we must remember that after the completion of I find in the stomach-contents micro- intact, meat-shreds and starch-granules. be placed upon the microscopic exam- omitus should, therefore, be subjected described later for the expressed test- wever, not be very valuable, because with the character of the food ingested stion. Free hydrochloric acid should, ric juice within one to two hours after

eating an ordinary meal; and the fibrin or coagulated albumin.

Furthermore, the examination of clusions about the gastric motility food more than seven hours after a must exist, for after that interval ev- pletely left the stomach. If this late perhaps, a larger amount be vomited a very pronounced motor insufficien *gastric dilatation*, may be assumed..

food known to have been ingested (seeds of fruit, etc.), suc

If we can show that the excess ingested at the last meal consists largely free hydrochloric acid, we are en gastric juice. The vomiting of an from a fasting stomach is especial In the latter case the secretion of not depend upon the ingestion of f secretion, *gastrosuccorhea*). We m some of these cases, and perhaps in is due entirely to a motor insufficien

is continually excited in a stomach which never empties itself completely. In contrast to these cases of hypersecretion in the strict sense, there are others characterized as *simple hyperacidity*, in which the vomitus is not abnormally abundant, but is abnormally and intensely acid (due to free hydrochloric acid). The method of determining this is by titrating the filtrate for its acidity. It will be described later. A quantitative comparison with the normal is, however, justifiable only when the vomiting occurred one or two hours after the meal, and when longer-retained food portions are not mixed with the vomitus. It was formerly assumed that both the motility of the stomach and its power of absorption are affected if a considerable quantity of a fluid which makes no demands upon digestion, such as water, coffee, etc., be vomited several hours after ingestion, and if the acidity of the fluid do not indicate hypersecretion. For it was claimed that, physiologically, the absorp-

Fig. 202.—Gastric contents from a case of benign pyloric stenosis. *Sarcina ventriculi*, large and small forms, fat-drops, and starch-granules.

tion even of large amounts of fluids by the stomach is exceedingly rapid. But von Mering's investigations show that under physiologic conditions the stomach absorbs hardly any water, so that the latter factor seems incorrect, and therefore we must attribute the retention of fluids as due to *deficient motility* alone.

An examination of the vomitus gives us important information about the *antiseptic qualities* of the gastric juice. Decomposition in the gastric contents depends either upon a diminution in the amount of hydrochloric acid contained in the secretion (for the acid acts as an antiseptic) or upon stagnation of the gastric contents, *i. e.*, upon some interference with the motility of the stomach. The vomitus is then apt to be foamy and to smell of some of the volatile fatty acids (butyric acid, acetic acid, p. 452), or to have some other disagreeable odor; and microscopically we find abundant micro-organisms, especially *Sarcina ventriculi*, yeast fungi, cocci, and bacilli (Fig. 201). This con-

dition is most pronounced in a dilatation of the stomach, especially from carcinoma of the pylorus, where the mucus is found in the stomach as a result of mechanical obstruction. We frequently find in carcinoma of the stomach, mucus in gastric dilatation due to other causes, present in long threads (Boas-Oppliger's test, and Bacteriologic Examination of the Gastric Contents (Fig. 201). Cocci and bacilli are usually present in gastric juice which is poor in hydrochloric acid, and yeast fungi may flourish in gastric juice. We meet with two types of gastrosuccorria (corruption of gastric juice). In both, the stomach is found with free hydrochloric acid, and this is apt to be the case. In the milder type this material is found in the vomitus. In the more severe type the large amount of mucus is no longer capable of keeping the stomach contents from becoming putrid, and micro-organisms grow abundantly, owing to insufficiency of the acid. In this case chiefly yeast fungi are found in the vomitus, and may be present in abundance in the gastric juice. HCl.

It must be noted that bread itself contains great numbers of yeast-cells. Hence, before conclusions are justified from the examination of the gastric contents after the ingestion of bread, a similar examination of the bread must be made.

Abundant tough, slimy masses in the vomitus are found in catarrh of the stomach or a diminution in the secretion of the stomach under normal conditions the mucus produced by the stomach is in part digested. (Compare later Examination of the Secretion of the Stomach.) An admixture of blood in the vomitus under many different conditions is of no diagnostic value, for the violent act of vomiting may produce a mechanical lesion of the stomach, esophagus, or duodenum, or an admixture of fresh arterial blood or of blood which has been coagulated by the acid gastric juice is especially common in the vomitus of the stomach. Cirrhosis of the liver is also responsible for the presence of hemorrhage. Brown or black material resembling coffee grounds, granular and intimately mixed with the stomach contents, is found in the vomitus of gastric carcinoma; but the same condition may be found in hemorrhagic erosions of the gastric mucous membrane associated with hyperacidity or hypersecretion of the stomach. The appearance is due to the altered blood by mechanical action, or by Teichmann's test.² (See Examination of the Gastric Contents.)

Pus may be found in the vomitus, due to the presence of purulent or phlegmonous gastritis. Admixture of bile in the vomitus or greenish discoloration of the vomitus. I apply Gmelin's test for biliary pigment. (See Examination of the Gastric Contents, p. 575 et seq.) Admixture of bile may occur in the vomitus, for the contents of the duodenum may

¹ Sandberg, Zeit. f. klin. Med., 1904, vol. li; also J. Clin. Med., 1905, vol. vi.

² The author recommends the modification of the benzidine tests described under Examination of the Gastric Contents.

ly by the act of vomiting. It is, however, observed most in vomiting from the fasting stomach, perhaps because there counterpressure from gastric contents to prevent the regurgitation from the duodenum. For the same reason biliary vomiting is seen in duodenal stenosis. The vomitus of *cerebral meningitis* is never mixed with bile, because these patients still take nourishment, and the vomiting generally starts with a paralytic stomach, i. e., the vomiting in this disease is both peripheral and central in origin. Green biliary vomitus is, of course, by no means pathognomonic of peritonitis.

Vomiting is a characteristic sign of complete motor insufficiency of the intestines (in peritonitis), or of *intestinal obstruction* in the lower part of the small intestine or in the large intestine. The odor and color of the vomitus are distinctive. Microscopically, it is usually found to contain large numbers of bacteria. *Cholera nostras* and *cholera asiatica* are characterized by the vomiting of abundant *alkaline rice-water* material (exactly like the cholera stools). It usually contains large numbers of mucus. In cholera Asiatica, the comma bacillus (see Examination of Feces) may be found in the vomitus. We are not certain about the organism of cholera nostras. The Finkler-Bacillus, the colon bacillus, various forms of the proteus, and streptococci (see Pathognomonic Bacteria of the Feces) have been found in the feces, and also in the vomitus of cholera nostras. The presence of streptococci in the vomitus has assumed some importance recently in the etiologic diagnosis of other gastro-intestinal infections. (See later Pathogenic Bacteria of the Feces.)

Color, odor, and chemical examination of the vomitus may sometimes be of use in tracing the occurrence of stomach disturbance to some sort of cause (prussic acid, alcohol, etc.). In uremia the vomitus usually possesses the odor of ammonia, for the urea eliminated in the stomach contents may be converted into carbonate of ammonia while in the stomach. (See note on p. 498 for the demonstration of this in the vomitus.)

Intestinal worms, more especially ascarides, are sometimes found in the vomitus. (See later, Animal Parasites in the Stools.)

It is sometimes difficult to decide whether food particles which the patient spels from the mouth come from the stomach itself, or whether they are only regurgitated from the esophagus (*diverticulum from stomach*).

The presence of free hydrochloric acid will usually determine this.

POWER OF ABSORPTION OF THE GASTRIC MUCOUS MEMBRANE BY MEANS OF POTASSIC IODID

We have published a direct method of testing the absorbing power of the gastric membrane. The procedure depends upon the principle that, under certain conditions, potassic iodid is very rapidly absorbed by the gastric membrane and then eliminated immediately in the saliva. The time of ingestion of the potassic iodid until the saliva exhibits a blue color may be considered as a measure of the rapidity of absorption. Differences in the time of elimination be neglected. The iodid should be in a gelatin capsule filled carefully enough to avoid any leakage to the outside, and so liable to be absorbed by the

Berlin. klin. Woch., 1882; Zweifel, Deut. Arch. f. klin.

To demonstrate the iodine, the p a little starch powder is added to the fully, 1 cc. of dilute sulphuric acid are added. The nitrous acid sets iodine produces the well-known violet color the iodine to iodic acid, which does not fore, be added drop by drop and stir remain any length of time in contact starch to erythro-dextrin and achro-dextrin colorless or only pinkish combination promptly. If a few drops of chloroform acid, the chloroform will dissolve the iodine is now recommended instead of nitrous iodine.

Experience shows that under normal in the saliva ten or more minutes after upon an empty stomach. If, however simultaneously with the drug, the experiment should always be performed accidentally with a test-breakfast. Based experiments, that if the drug were taken appeared in the saliva, under normal. If retention be suspected, the stomach the reaction be delayed, although this is the probable cause, because experimentation of the reaction in an absolutely normal conditions.

Of course, this method does not food substances, for, as a matter of favorable pathologic conditions, is abnormal.

If v. Mering's¹ experiments be correct less. He finds in dogs, and very likely is not absorbed at all from the stomach we must acknowledge that the rapid depends upon the absorption of the iodine measure of the gastric motility. However called into question by Boas.²

EXAMINATION OF THE MOTILITY OF THE

Palpation (p. 426 et seq.), especially gives us some idea of the gastric motility (p. 427 et seq.). Ewald and Sievers ment of salol to test the motility. the stomach unchanged, and splits salicylic acid and phenol, under the influence of bacterial bacteria. Salicylic acid, soon converted salicyluric acid (ferric chlorid produces Examination of the Urine). Assuming rapidity, this reaction should measure time; in other words, the gastric motility.

Ewald and Sievers administer the urinates at regular intervals during the performed upon each specimen. No seventy-five minutes. If delayed beyond insufficiency may be diagnosed.

This method of testing is beset with one is that we can never be sure when a uniform mixture of the salol and leaves the stomach with the first portion depend upon chance. Hence the salol else taken in small portions (as an emulsion).

¹ Klin. Jahrb., 1899, vol. vii; also

² Arch. klin. med., 1904, lxxxi, 51

up, of absorption, and of elimination is not always a definitely fixed quantity. The author's investigations with glutoid capsules have great variations in the intensity of proteolytic action of the pancreatic

However, in spite of these sources of error, the method gives quite information regarding the more pronounced disorders. In marked gastric the salol may remain for hours in the stomach.¹

modified this method by determining the length of time which elapses the salicyluric acid is excreted. The reasoning is clear. The moment appearance of the salicyluric acid reaction depends principally upon the which the stomach passes the first amount of salol into the intestine; persistence of the reaction in the urine (assuming rapid splitting up and ation of the salol in the intestines) is due to the fact that the stomach passed on all the salol. Therefore the duration of the salicyluric acid y be a better measure of stomach motility than the period of its first

Huber's investigations have shown that in healthy individuals who 1 gm. of salol at a meal the salicyluric reaction has always disappeared enty-six or twenty-seven hours. Motor insufficiency may therefore be this time be exceeded. With this method the urine need not be tested twenty-seven hours after taking the salol. Of course, the urine should little beforehand, *e. g.*, one-half hour, so that no residual urine remains. uric reaction be present twenty-seven hours after the ingestion of the t should be repeated every three hours until it disappears. The degree of iciency is in direct proportion to the duration of the reaction.

and Huber's methods may be combined as follows: 1 gm. of salol is the meal, either intimately mixed or in very small quantities, and then appearance and of disappearance of the salicyluric acid in the urine is

l tests will reveal impairment of motility in all sorts of stomach disorders. nce of the reaction may be delayed for several hours, and not infrequently or forty hours or more.

has recently been recommended by Winkler and Stein instead of salol. free and absorbed in the intestines and then tested for in the saliva or uarter to a half hour after a test-breakfast the patient is given a small of iodipin containing 10 per cent. of iodine, and the urine or saliva is very fifteen minutes for iodine. Normally, iodine reappears in from sixty five minutes. Fleischer has also used iodoform for a similar purpose (taining 0.1 gm. of iodoform). The iodine reaction in the urine and saliva mally at the latest in one and three-quarter hours. The examination is more certain than that of the saliva. (See p. 507.)

hor is convinced that none of these methods is perfectly trustworthy ng the gastric motility. In the first place, we are not sure that the employed are intimately mixed with the gastric contents, nor are we they may not be precipitated by the gastric juice and reach the intestines too late. Again, the results will be very decidedly influenced by the he splitting up and of the absorption in the intestines. If von Mering's rmed (see p. 432), that potassic iodide is not absorbed at all in the en Penzoldt and Faber's method for testing the absorption in the stomach sed as a test of its motility (p. 431 et seq.). Further investigations int are necessary.

THE DIGESTION WITH POTASSIC IODIDE FIBRIN-RUBBER CAPSULES .

h this method was detailed at length in a previous edition of this book, led to no practically useful results, and so it need only be alluded to.

THE DESMOID TEST

Correspondenzblatt für Schweizer Aerzte, No. 8 and 9, 1905, the author method which was based on the fact, discovered by Kühne and Schmidt, nective tissue is not attacked by the digestive ferments of the intestine

s, however, reason to believe that in cases of grave disturbances of motil- e salol remains for hours in the stomach, some of the drug may also be this organ. Part of it is, perhaps, first split up by micro-organisms, rely absent in a stagnant stomach, or by the fat-splitting ferment of the uch a slow absorption, however, would rarely, if ever, lead us to assume tility was normal.

but is dissolved in the gastric juice. This test. With this test one may arrive at certain conclusions of the stomach without the aid of a stomach-tube of this instrument from the diagnostic armament action is similar to that of the glutoid test, in the excretion of a substance contained, either in a mastic capsule, after its liberation from its capsule of iodoform, the iodine of which is detected in the mastic blue, which may be excreted in the urine as the mastic less chromogen. If one of these small containers of gastric juice will dissolve the connective tissue with the indicator. The latter will be absorbed and excreted.

Preliminary trials showed that catgut or gold-beater's skin or by putrefactive processes. Preliminary trials with pepsin-hydrochloric acid, short of solution, does not. Clinical experiments showed that neither the sucrose was capable of acting upon them. Catgut is selected to the test than the gold-beater's skin.

The materials used in the test are the following:

(1) Rubber membrane of the finest Para rubber. This membrane is 0.2 mm. thick, and can be obtained from the Rubber Chemical Company, 100 Avenue, Brooklyn, N. Y. The membrane is light yellow. It is a product of the above-mentioned firm for the test.

(2) Catgut of the finest quality, 0.3 mm. thick.

(3) Pills made exactly after the following formula. They are perfectly hard and subsequently dusted with lycopericon.

(a) Iodoform.....
Ext. glycyrrhizæ.....
Pulv. glycyrrhizæ.....

Divide into 50 pills.

(b) Methylene-blue (medicinal)
Ext. glycyrrhizæ.....
Pulv. glycyrrhizæ.....

Divide into 50 pills.

More recently the author has used pills which sink at once in the stomach-contents.

They are composed as follows:

(a) Iodoform.....
Pulv. glycyrrhizæ.....
Bismuth. subnitrat.....
Glucose syrup (sat'd).....

Divide into 200 pills.

(b) Methylene-blue (medicinal)
Pulv. glycyrrhizæ.....
Bismuth. subnitrat.....
Glucose syrup (sat'd).....

Divide into 200 pills.

These pills are hygroscopic and must be kept in a dry place. These pills are placed in the stomach must be prepared fresh each time.

Preparation of the Desmoid Sacs.—A piece of rubber membrane is immersed in water until it is soft, then removed, and the hands must also be quite dry. From this a piece of membrane is cut out and sprinkled with talcum powder. The pill is then placed in the center and the corners taken up. The membrane must include the pill completely in the membrane by twisting (See Fig. 203.) The torsion employed must not be too tight. A portion of the sac is tightly held by the thumb and the right hand may be released. The next manipulation is to twist the membrane. This requires a little practice. One end of the catgut is inserted into the sac and the catgut wound three times round the neck. This is done to prevent burying the strands of the

venting contact with the gastric juice. At the same time the winding must be done in such a way as to avoid the further stretching of or cutting the india-rubber. The catgut is finally secured by a double knot. Both knots must be on the same side of the neck, else in order to loosen the neck the digestive action must occur at both knots. (See Fig. 203.) The rest of the dental membrane is cut away at a distance of 3 to 5 mm. from the ligature. It is better not to cut the free end of the rubber in one cut, but to take a single layer and gradually cut it away. In this way one avoids sealing two layers of the rubber together by pressure from the scissors. The sacs sink in water, and leave the stomach with the last portions of the meal. It is well to ascertain whether they actually sink in water or not. If they do not, the rubber may be cut a little closer to the ligature. The bismuth pills sink in a fairly thick chyme, especially if they be taken immediately after soup. The sacs must be perfectly water-tight. Those containing methylene-blue must not release any of the coloring-matter when allowed to stand in water at body temperature for twenty-four hours.

Method of Use.—The practical details of using the sacs are as follows: Immediately after soup at lunch the patient swallows the sac with the aid of a little water. It is not advisable to inclose the sac in a gelatin capsule, for the air in the capsule will

Fig. 203.

allow it to float. The pills can be used one after the other, if the methylene-blue pill be used first. The detection of iodine in the urine is not disturbed by the presence of methylene-blue. The sacs must be swallowed carefully in order to prevent their rupture by any untoward movements of mastication. In swallowing them it is better for the patient to hold the head well back. The patient may now go about, but in those confined to bed it is necessary to caution them not to lie on the right side, for in that case, in consequence of the high specific gravity of the sac, it is not brought into contact with the gastric juice before it reaches the pylorus.

The patient is told to urinate at 5 P.M., at 7 P.M., and on rising the next morning. These three samples of urine must be collected separately. The elimination of the methylene-blue may be seen immediately by the color it imparts to the urine. In case the urine is not colored, the chromogen, if present, may be converted into the coloring-matter by boiling 10 cc. of the urine with 1 cc. of acetic acid for two minutes. The presence of the chromogen has the same significance as that of the coloring-matter itself.

A positive reaction is obtained when the methylene-blue or the iodine appears in the urine of the same evening or the morning following. Otherwise the test is negative. To test for iodine the urine is first shaken with animal charcoal, after heat-

ing gently, in order to remove the color coal is filtered off, leaving the urine pi removed by the addition of a little ca Huppert's test for bile-pigments. To d and 0.5 cc. of a 1 per cent. solution of so To this 2 cc. of chloroform are added. If to the chloroform.

Significance of the Result.—A positive reaction for iodine in the urine of the same evening, in connection with pepsin-hydrochloric acid digestion, is in complete agreement with the statements to the contrary, the author believes that, if made properly, the catgut is not dissoluble in intestinal putrefaction. The method allows of the catgut being taken at the same time as the sac, has no effect on the stomach. Further on, the author will draw definite conclusions are based on a safe method of examination performed with the desmold test, and in the preparation of trypsin in soda solutions, 1 per cent., did not dissolve the catgut in 10 days, carbonate, in spite of very active putrefaction. In solutions of 2 per cent. sodium carbonate, after four days. In pancreatin solution the catguts were prevented by the addition of chloroform for 3 months. In pepsin-hydrochloric acid digestion experiments have been confirmed on rabbits and dogs, desmold sacs in the region of the pylorus, stomach, and found that the catgut was not dissolved. who claims that catgut is slowly dissolved in intestinal extract, are absolutely unconvincing. Catgut activated by intestinal extract is capable of being dissolved is not comparable to intestinal juice. Catgut does not play a part in the solution of the gut. Catgut digestion by intestinal secretions is seen in Schminke's experiments. They are also confirmed by the results, with exception, negative.

A negative test proves that sufficient may depend either on a deficiency in the motility of the stomach, in which latter from the stomach.

A delayed reaction, occurring in the test-meal, shows that gastric digestion is incomplete. If the acidity of the stomach is interfered with, as in case of atrophic gastritis. The writer has been able to show that in the test-meal, in the afternoon or evening of the day, in the stomach the following observations are made: the desmoid reaction would indicate whether or not the ingestion of a meal, and that a positive reaction to hydrochloric acid. This, however, is not the case where free hydrochloric acid is absent. The reverse also occurs. At the outset, the inconsistencies to a fundamental error in the test-meal, that they show the insufficiency of the test-meal contents of the stomach and the true acidity of the contents. These apparent inconsistencies are the result of the arbitrary one, and at the same time is not a true test, and it cannot be said that the acidity of the test-meal as after a meal more suited to excite the gastric secretion. The author has satisfied himself that the desmoid reaction is positive, and no reaction is obtained after the ordinary test-meal, the gastric juice three hours after the test-meal, the total acidity is greater than that in the test-meal, be that of Ewald-Boas or the flour-sour test. The desmoid reaction is also positive in the test-meal, while the test-meal is a much less accurate test, the digestion may proceed, even in the

of albumin has been observed in Mett's tubes when all the free hydrochloric combined with albumoses, and the mixture did not react to Congo-paper. condition necessary is that the total acidity must not be too low and the albumoses too high. With low acidity and much albumoses, albumin may be dissolved in vitro. It must, however, be pointed out that in this test the acid is taken up directly from the gastric juice, while with the desmoid test, the sac, on account of its high gravity, comes into direct contact with the wall of the stomach. The conditions are, therefore, much more normal than in the test-tube examination. Further, one must remember that any investigation dependent on siphonage concerns the contents only at a particular time, and the results may be quite different from what might have been obtained before or after a meal. All these possibilities must be borne in mind, but the principal one, in the opinion of the author, is due to the great difference in the quality of the two tests. The desmoid test is given with an ordinary meal, which favors the presence of free hydrochloric acid. This is not the case with the usual test-meal. These conditions show clearly how imperfect is our knowledge, with the best of the diagnostic methods for examination of the functions of the stomach, the butyrometric test notwithstanding. The presence of hydrochloric acid in the gastric contents is due to many factors, and also to the rapidity with which the chemical conditions change in the organ. It is, therefore, an important fact that in the desmoid test there is a means of investigating the gastric digestion under strictly normal conditions. The fact that even in the presence of free hydrochloric acid the test sometimes is negative is easy to explain. Either the amount of acid is not sufficient for the digestion of the larger meal, the pepsin is not in the proper amount, or it may be that the motility of the stomach is excessive. This last condition indicates insufficient gastric digestion, although the secretion itself is amply active, because the contents of the stomach are not retained in the organ for the proper length of time. An illustration of the latter condition was afforded by a case of hyperacidity with gastric stasis operated on for a cicatricial stenosis of the pylorus. The patient benefited by the operation, although obviously the stenosis had been relieved. The desmoid test was negative, showing that the sac, in consequence of its low specific gravity, had fallen to the lower part of the stomach, and had been washed out with great rapidity into the intestines, and thus had escaped the action of the gastric juice. There was, therefore, besides the beneficial effects of the gastro-enterostomy, an elimination of the physiologic effects of sedimentation in the stomach, a factor which has been so clearly pointed out by Moritz. The condition of the patient was, therefore, not improved by the operation. This fact must be borne in account very seriously in any contemplated operation for gastro-enterostomy. In the event of any indication which is not perfectly clear the operation should be deferred. The desmoid test shows that gastric digestion cannot be entirely replaced by intestinal digestion, as is very often supposed, and it is quite impossible to determine beforehand what the effects of gastro-enterostomy may be. The author does not present these facts forward to minimize the importance of the operation where it is indicated, as, for example, in severe partial mechanic occlusion of the pylorus, but to show how insufficient is the basis for assuming that gastro-enterostomy is a panacea for all possible disturbances of the stomach, either due to neurotic conditions or true new-growths of the organ.

From the standpoint of practical diagnosis, the desmoid reaction appears to be of value in those groups of cases where the investigation of the gastric contents shows the absence of free hydrochloric acid, simple cases, as distinguished from those in which the absence of free hydrochloric acid is connected with pernicious anemia or gastric carcinoma. These cases are recognized by the fall in the total acidity. In the less severe cases the test may be positive in spite of the fact that the total acidity is low. This is due to the stronger stimulus as the test is negative, because the strongest secretion of pepsin and hydrochloric acid, which the stomach affords, is used in the test, and thus affords a better indication of the functional capacity of the stomach for the detection of free hydrochloric acid. In the case of the total acidity and the amount of pepsin, the test is usually done. The desmoid test is a capacity of the stomach, through the difference in the gravity of the contents, comparing this test with the others commonly found to be erroneous.

In those cases which, in spite of conditions, give a negative result, these cases give an interesting confirmation of the stomach as a retaining mechanism. He showed

that substances difficult to digest, provided they be retained in the stomach for a considerable time, and pass on to the intestine would give a negative result. The retention of the teleologically important food, by reason of its capacity for retaining its form, in case of gastric insufficiency the stomach may retain the food in order to complete its digestion, while in the case of pernicious anemia, as is encountered in pernicious anemia, the stomach is not motile, as if by instinct it reacts to the food by the retention of the food in the organ.

The author also wishes to point out the anomalies of the digestive function of the stomach as determined by ordinary methods, for neither the acidity gives us results which enable us to detect disturbances of gastric digestion.

In order not to be misunderstood regarding the desmoid test, it should be said that the test is not a measure of the capacity of the gastric juice on connection with the stomach has to perform, but, at the same time, it is a measure of the meal itself. This is indicated from the fact that if a meal is well digested give a positive test, the action of the digestive juice must be sufficient to digest the meal.

To this extent, the author believes that the test is a reliable method of testing gastric efficiency under normal conditions. Furthermore, it is possible to use the test in determining the quality of a meal suitable to provide for the needs of the patient.

In conclusion, it may be said that the author's views on the physiology and pathology of the stomach, and the tests, permits us to examine the chemical conditions of the stomach.

If the author may be allowed to comment on the objections which have been raised against the method, he wishes to state that the differences which have been found between the results obtained with a test-meal and the results obtained with a test-meal read the author's original papers, and do not show any differences, and has shown that these variations are due to the desmoid reaction itself. If certain variations are found because of the digestion of the catgut in the stomach, without offering any experimental proof of the scientific ability of the author, for he has shown, by his experiments, that this is not the case. Since the author's assistant, Wölfer, who has repeatedly performed gastro-enterostomy, and has found that the desmoid reaction is without exception negative, the author believes that the desmoid reaction is without exception negative. Pepsin may also act proteolytically is not to have more academic than practical in such a condition in the stomach, for the desmoid reaction is necessary for so difficult a digestive process, but seldom in the stomach. Furthermore, the author suggested that the desmoid reaction is a reliable method for a chemical examination of the gastric contents, and for the functional peptic activity of the stomach. In individuals with good gastric digestion the desmoid reaction is negative.

¹The author has made gastric examination where the desmoid reaction was negative, in the case of latent anacidity, or, in spite of the presence of free hydrochloric acid, or a poverty in ferment, or a hypermotility of the stomach, and where the food passed quickly through the stomach and where the undiluted gastric contents be examined on p. 473, without the addition of hydrochloric acid. The gastric juice containing both free hydrochloric acid and ferment be quite inactive, due to the fact that the desmoid reaction was negative. It was through this important finding, which led to the discovery of the desmoid reaction, that the author led to take up the desmoid method, and to study the physiology and pathology of the stomach and the desmoid reaction.

be dealing with hypermotility; and, as the author has observed a negative result with hearty eaters, he assumes that where the intake of food has been excessive much of the food may pass through the stomach undigested, as an examination of the stools often reveals, despite the fact that the individual may feel perfectly well. The desmoid reaction gives the situation exactly as it is in the stomach, not to be concluded from observations made with the test-tube. The author believes in this fine power of distinction, which the desmoid test possesses, is the reason which it has made to progress in gastric diagnosis.

This method is so well founded physiologically that one may question whether it is suited as the basis for explaining certain clinical paradoxes which do not agree with the ordinary views on gastric digestion. It seems to have a better right to trust to the absolute infallibility of the latter. In any event, it does not seem a waste of time to discuss criticisms based on the assumption that the author has endeavored to replace the chemical examination of the gastric contents. In fact, he has used them to supplement the test, to point out that many of the tests have been carelessly prepared, or have been made without reference to the method.

The desmoid test does not, and should not always, give a true examination of the contents of the stomach, to Gentsen, if the test be made in the morning when the stomach is regularly positive.

In the morning to patients who have fasted since the previous evening until the reaction appeared. He found that the reaction occurred in six to seven hours at the latest; it occurred earlier. He concludes, as has Schreiber, from siphonage of the stomach in this condition contains a peptically digested food of administrative interest. The desmoid test a test for free acid, with a constant result and a positive desmoid test, and conversely, cannot at this moment be said, for cases with

of free hydrochloric acid have not so far been observed. As one will see, the test fails to give information regarding the digestive act after the administration of ordinary meals.

METHODS OF EXAMINING THE STOMACH WITH THE AID OF THE STOMACH-TUBE

INSTRUMENTS

Dr. Kaul was the first to employ the stomach-tube for the treatment of gastric affections, and von Leube the first to use it for the diagnosis of gastric affections. With its help we can at any time obtain the gastric contents for examination. We can also distend the stomach to any degree for diagnostic purposes. Unless there be a stenosis of the esophagus or cardia, rubber tubes which are quite soft and pliable are to be preferred. The surface of the tube must be smooth, the rubber soft and collapsible, the lumen large in relation to the entire diameter, the opening at the lower end as large as possible. The smaller-sized tubes are generally easier to pass and less disagreeable to the patient, but they are more easily stopped up. In passing the smaller sizes we require the patient's help in swallowing, whereas the larger can be more readily passed down the esophagus. No. 22 (Jack's patent),¹ with a diameter

of .08 inch, is suitable for cases of negative desmoid reaction have become common. These sink at once to the deepest part of the stomach, the patient to assume a standing or sitting position, any recumbent position except that on the back, the tube being carried by gravity into the duodenum.

It is very good, but a rather softer and more pliable tube, especially upon the first introduction. We refer to the *Stomach*, second ed., pp. 114-118, for the introduction of the tube.—Ed.]

of about 12 mm., is, the author believes, they are provided with a lateral opening and p. 445 in regard to the advantages of the new design. Near the lower end instead of one lateral opening the author devised the former for complete emptying. In the Bern clinic they are used exclusively with the aid of a small glass tube for connection. The tube is about 1 foot long, the stomach-tube is connected to the glass. [A funnel made of black vulcanite is used for the withdrawal of the material. It is also less than 1 foot long. Three pieces together constitute a siphon and we can easily empty and wash out the stomach. A rubber bulb may be substituted for the funnel. The device permits the use either of pressure or suction. Compression of the tube takes the place of the funnel.]

In inflating the stomach to determine its capacity, this bulb or a so-called stomach-pump, with a two-way stop-cock, so that the barrel of

Fig. 204.—Stomach-pump.

with the stomach-tube or opened to the atmosphere by means of a lever controlled by the hand the pump can be readily turned.

The stomach-pump formerly in common use is now unnecessary and not to be recommended. No suction is afforded by the siphon apparatus and bulb device. Suction may easily detach bits of the gastric mucosa. Use of the bulb is not advisable for emptying the stomach. It is unnecessary if the directions given on p. 442 be followed. The value in freeing the tube when the latter is clogged should be done by forcing air through the tube rather than by suction.

TECHNIC OF INTRODUCING A STOMACH-TUBE

The patient should be in the sitting position with the head open. The operator supports the patient's head and introduces the tube with his right wrist into the patient's mouth. The rounded end of the tube is pushed up and down over the base of the tongue, and then down the esophagus, where there be no obstruction in the esophagus, with anything but water. If the patient can breathe quietly and deeply, the tube can be introduced.

THE VARIOUS STEPS IN THE

The best time to introduce the tube is on a fasting stomach, the patient having ingested a rather abundant mixed meal.

We first cleanse the fasting stomach, by the irrigation which it may contain. After the patient, in the recumbent posture, is gently, to aid in expelling any stomach-contents, the attempt is repeated with the patient in the erect position. After the evacuation, or if nothing is expelled, a little lukewarm water, and later a pint of water, are introduced into the stomach again by depressing the funnel. If employing a funnel, the examiner must see that the tube does not become empty, and that the water is not drawn back. In case any particles stop up the tube, it is cleared by drawing the water back into the stomach by elevating the funnel, and forcing it through with the bulb. Strong aspiration is not to be employed with the bulb or the stomach-pump, for fear of forcing the obstructing particles forcibly through the pylorus on account of the danger alluded to above. The irrigation is continued until the returning fluid is clear, and free from interference with the test-meal given later, it is changed to warm water. This can best be done by using the funnel and the method described on p. 445 et seq. If the tube is removed before beginning the washing, it should be replaced. (See p. 446.) If this was not possible, the attempt is made at the first dilution.

After emptying and cleansing the procedure is to determine its size and position with water. This can be accomplished with the rubber bulb [or a Davidson syringe.—the dorsal decubitus, with the lower chest. We must inflate cautiously and stop when too great tension results. After it is made will generally disclose the size and shape, not, however, correspond to those of the filled with food. (See p. 424.) Nevertheless in this way. The position of the semilunar curvature is of greater significance in this re curvature, and in inspection of the inflated the position of the lesser curvature as well confusing a gastropnoxis or loop-shaped stomach logically dilated.

The "hour-glass" stomach is very rare, connected by a constricted passage, and can be recognized by inspection of the inflated

¹ This will be superfluous if we have already by inspection, by palpation, and by percussion.

TESTING THE GASTRIC FUNCTIONS BY

The principle involved follows: The mined meal upon a fasting stomach, if emptied artificially or the first thing conclusions as to the functions of the from the chemical character of the contents the lapse of a certain time.

Various test-breakfasts have been used; one kind is better; for others, another to test the behavior of a certain food should be selected for a test-breakfast. A behavior of the stomach under an ordinary meal for our test, *e. g.*, Riegel's test-meal: mutton broth, a beefsteak (15 to 200 g.) and a roll. The test-meal should be given usually eaten, for Marbaix¹ has shown that to provoke an abnormal secretion from a test-breakfast is the most serviceable food and uniform. It consists of one roll (about 100 g.) of white bread, and two cups (400 cc.) of milk or sugar. The patient should chew it. More useful and accurate information was obtained by Seiler's Butyrometric Test-breakfast."

The meal is allowed to remain in the stomach until acted upon by the gastric secretion, and then the tube is inserted and the contents are aspirated. Riegel's meal is ordinarily given at 10 hours; the Ewald-Boas and the "butyrometric" hour. If no contents can be obtained at 10 hours, another meal should be ingested, at 11 hours. Conversely, if information by the stomach requires to empty itself completely, the meal is repeated and the meal extracted after a lapse of 1 hour.

The Ewald and Boas method of expression is the best of obtaining the stomach-contents. The stomach is expressed by the tube and strained down. The food is usually expressed in the right or left lateral, rather than the anterior, position. If the tube becomes clogged, we can generally express through, which is more convenient than through more water. When but little is expelled, we are sure, so as to be sure that the stomach is completely emptied. The amount of the meal which is expressed (See p. 482 in regard to the procedure). If the method for completely emptying the stomach is to be employed, this procedure is entirely satisfactory.

A PROCEDURE FOR THE COMPLETE EMPTYING OF THE STOMACH

The method of expression described above is the best for ascertaining that the stomach is completely emptied. The lavage of the stomach gives, to a certain extent, completeness, but does not afford quantitative results. The so-called residue estimation has, with proper care, been found to be satisfactory.

¹ Marbaix, La Ce

utility of the stomach, the stomach should be used in the method which he has used. This procedure is completely safe. The contents of the stomach may clog the tube. For this reason the Riegel or Ewald is used. The opening of the tube is directed upward, and project after part of the con-

a stomach-tube of the opening, possesses a the lower end. They

III

Final posture, in which the total gastric contents escape through the tube.

Position of the stomach by means of the radiograph of a siphon-

and are placed more or less introduced until the tube is in the stomach. The usual way, with the tube has ceased, the external end of the tube is held well, and holds the left lateral end of the tube.

One of the openings of the stomach is the lowest point of the contents of the stomach. With the aid of gentle pressure the schematic relations of the stomach in a condition which interfere with the ordinary openings which the patient, one of the

openings must lie at the deepest level of form of the stomach must be taken into account. A quantity of the fluid could be trapped in the stomach even when the cardia was the lowest point. The author recommends the patient to retain the left lateral position to bring the body over the edge of the table to show, if this be done, even with a very marked pyloric end will be completely emptied of its contents. He is completely convinced, by experiments without the stomach after this procedure, that the clots which may adhere to the mucosa are left in the stomach during this process as a very distinct advance in regard to the objections which were raised to the butyrometer. Inability to empty the stomach completely for therapeutic purposes, for lavage, and for cleansing the stomach after administration of a test-meal, the procedure of the author. [Since adopting the author's method of examination, he has succeeded in recovering a sufficient amount of gastric contents for examination, and venture to commend it to others.]

The stomach in the knee-chest posture may also be examined with the stomach-tube, but the position is not so convenient. Several openings be not available, one may place the tube in the stomach and gradually withdraw the tube, until the opening is reached. A suggestion to replace the multiple opening tube by a single tube has not been accepted.¹

EXAMINATION OF THE CONTENTS OF THE STOMACH

The materials removed from a fasting stomach should be examined in the same way as the vomitus, so far as their mechanical and chemical peculiarities are concerned. For the chemical examination the same rules apply as for testing the expressed breast milk. If the fasting stomach contain remnants of a meal, there must be a considerable degree of motor insufficiency. In a normal stomach would be empty within a few hours after a normal meal, and in any event by the next morning.

Cranberry or Currant Test.—If we have no other method for determining motor insufficiency, the test may be accomplished, according to Ewald and Strauss, by giving the patient a meal, a tablespoonful of cranberry or currant juice. If a certain degree of motor insufficiency of the stomach exists, the next day contains any of the fruit or seeds. The test does not make any difference whether or not the patient receives ordinary nourishment.

If we can obtain from the fasting stomach a fluid containing free hydrochloric acid, hypersecretion may be diagnosed, because, if the stomach secrete only a small amount of hydrochloric acid, the gastric juice or of the saliva swallowed may suffice. Small amounts of fluid containing hydrochloric acid may be obtained for Schreike has shown, and later Gentzen has shown, that the fasting stomach contains a fluid containing hydrochloric acid. Hence a small amount of fluid containing hydrochloric acid.

¹ Zeit. klin. Med., vol. lxxv, 1915.

of acid fluid which can be remain within the normal individual authority. Ordinarily cases have been reported, noted without any noticeable physiologic for a fasting stomach. Between a physiologic and a morbid differentiate between primary stagnation, compare p. 1004. A fasting stomach is thin, not 1004 to 1005. It thus differs from acts of digestion, such as is food is retained. (Compare

that it is due to bacteriologic increased production of hydrosecretion of gastric juice

yellowish bile-containing fluid, from the stomach. It consists of vomitus. From the gagging and vomited examinations show that there have been no vomiting efforts, chronic disease, there must be a duodenal obstruction (Boas). Indicated by various authors.¹ The yellow color is really due to bile. The stomach contents in such cases secrete enough acid to produce an acid reaction. On the other hand, the stomach is atonic and the fluid is stagnant for some time and remains acid. In case the fluid comes from the duodenum it is an alkaline solution. For this reason it is colored with Magdalen's reagent, if necessary, with 1 per cent. soda solution. The color is retained in the fluid, and the acid reaction, it is usually negative for pepsin, because in acid solution of the gastric juice.

of trypsin, and for recognizing the Boas and Volhard-Boldireff reaction).

may sometimes be diagnosed by endoscopic and microscopic contrast method is to wash out the stomach and repeat the lavage the next day. Nothing overnight. Sometimes the tube for microscopic examination of bits or cells can thus often be used. The stomach may be considerably ulcerated. Only the sediment examined

EXAMINATION OF THE GASTRIC ORDINARY (EWALD-BO

The expressed breakfast is, first the filtrate is called the "gastric juice"

EXAMINATION OF S

As is well known, the salivary soluble starch (*amylum* to *amidulum*) the latter violet. The next change reddish to a mahogany-brown color and *maltose* are formed (not, as was last two products no longer produce

In testing the gastric contents for the point to determine is whether, in considerable quantity, even in the there are also the above-mentioned tests. With a solution of iodine this can be determined produces no color, but it has a

starch itself. Consequently, when slight traces of iodine are added to a uniform mixture of starch and achroodextrin, the iodine combines with the achroodextrin before it affects the starch. Therefore, if we add traces of iodine to a mixture of starch and achroodextrin, no color will result until an excess of iodine brings out the violet. A drop of a very dilute (wine yellow) Lugol's iodine solution¹ upon a glass rod is added to a small portion of the residue on the filter-paper, or even to the filtrate (because the latter always contains soluble starch). If achroodextrin be present, no color will appear until an excess of iodine is added. If, on the other hand, no starch digestion has occurred, the slightest trace of iodine will produce a violet color.

If a large volume of gastric contents be at our disposal, the test may be performed as follows: Lugol's solution (0.1 gm. iodine, 0.2 gm. potassium iodide, 200 cc. water) or centinormal iodine solution is added drop by drop to the filtrate. The amount added before a violet color appears will furnish an approximately accurate quantitative measure of the degree of starch digestion. The latter, of course, depends not only upon the rapidity of enzyme action, but also upon the degree of the absorption of the product formed.

Starch digestion is a function of the salivary enzyme. Its action is apparent partly in the mouth and partly in the stomach for a short time after the meal. Hence, starch digestion would naturally seem of little importance in the diagnosis of stomach diseases. But this is not really so, because an increased acidity will interrupt starch digestion very quickly. A blue color is obtained on the addition of the smallest quantity of iodine solution. On the contrary, with hypoacidity starch digestion progresses very favorably and completely. Hence, the degree of starch digestion serves as a rough test of the hydrochloric acid secretion. Boas claims that a digestive fluid containing 0.15 per cent. hydrochloric acid will arrest starch digestion. Nevertheless, even with normal gastric digestion, achroodextrin is present in the Ewald breakfast one hour after its ingestion. It was probably produced before enough acid had been secreted to reach the above degree of concentration. Achroodextrin is often absent in hyperacidity. Lactic acid does not impede starch digestion until it is more concentrated than hydrochloric acid, so that starches are frequently well digested in the gastric contents in hypomotility (Stauungsmagen) in case the stomach contains lactic, instead of free hydrochloric, acid.

QUALITATIVE EXAMINATION OF THE FILTERED GASTRIC JUICE FOR ACIDS

The reaction of the filtered gastric juice is, first of all, tested with litmus-paper. If the reaction be acid (as is almost universally the case), we get no information about the presence of hydrochloric acid, and especially of free acid, in the gastric juice, since besides acids, salts, particularly the acid phosphates, also turn blue litmus red.

To determine whether the acid reaction is due to free acid or only to acid salt we employ Congo-red, in the form of commercial Congo-red paper. If the gastric juice turn a strip of this paper blue, some free acid must be present: either free hydrochloric or some organic acid.²

¹ A few drops of tincture of iodine added to a 1 per cent. solution of potassium iodide.

² Congo-red is not at all changed by acids combined with proteins or with organic bases, and by acid phosphates only in such concentrations as do not occur in the stomach. The reaction may be regarded in the case of stomach-contents as one for free hydrochloric acid.

To decide whether the acid is organic various qualitative tests.

Tests for Free Hydrochloric Acid.—The presence of free hydrochloric acid in the gastric contents has been secreted by various tests of the stomach, especially the excess of acid remains. Concerning the presence of free hydrochloric acid, see p.

The reactions with methyl-violet, azobenzene have not proved satisfactory. The best for the purpose:

Congo-red Reaction.—Congo-red, when treated with the dye, is changed by color, but only in such concentrations as occur in the stomach. In any case the change in color is not due to free hydrochloric acid, so that a dark-blue reaction is evidence of the latter.

Phloroglucin-vanillin Reaction.—The reagent consists of phloroglucin 2 gr. dissolved in 100 cc. of water. One or two drops of this solution are mixed with the same amount of gastric juice and warmed over a small flame. If free hydrochloric acid is present, the drying margins of the mixture will develop a red color. If absent, the solution dries up, leaving a white residue. The reaction becomes a little more sensitive if the reagent is mixed with rather more gastric juice than reagent.

The phloroglucin-vanillin test gives evidence of 0.005 per cent. hydrochloric acid.

Tests for Lactic Acid.—Uffelmann's reagent is employed to test the gastric juice for lactic acid. It is a mixture of 20 cc. of a 1 per cent. solution of dilute ferric chlorid. This solution is added to the gastric juice and becomes a transparent amethyst blue. The reaction is observed before each test, since the violet color is easily destroyed. This is a very delicate reagent: even a trace of lactic acid turns it to a beautiful canary yellow or green without the formation of any pronounced precipitate. Lactic acid, because proteids, salts, and other substances give such a result. Uffelmann's reaction is not applicable to the fluid to be tested one or two drops of a 1 per cent. solution of ferric chlorid (without calcium chloride). If lactic acid is present, it will become distinctly yellow. In the case the same amount of ferric chlorid is added to a normal gastric juice for comparison. Uffelmann's reaction is not applicable to sugars, peptones, alcohol, tartaric, citric, and various other substances. An objection is that the reaction may be obscured by phosphates and a considerable excess of phosphoric acid. The addition of the ferric chlorid, may not be accurate. Accuracy will result if we isolate the lactic acid from the juice with ether, removing the ether by evaporation and test upon the ether residue dissolved in water.

by appropriately modified by H. Strauss.¹ By this method all errors are avoided and a quantitative result obtained.

Strauss' Method of Determining Lactic Acid.—He extracts the gastric juice with ether, but does not evaporate the ether. He shakes the ethereal extract with a dilute solution of ferric chlorid, according to Fleischer's method. If the lower layer shows a greenish coloration, the reaction is positive. By employing definite quantities of reagent and solution, the intensity of the coloration can be made to furnish an accurate estimate of the amount of lactic acid. The procedure is as follows: 5 cc. of gastric juice are put into a separatory funnel (Fig. 207) having two division marks, one corresponding to a volume of 5 cc. the other to that of 25 cc., ether is added to the 25 cc. mark. The solutions are then shaken vigorously. After the mixture has settled into layers the gastric juice at the bottom is drawn off by means of the stopcock. Distilled water is then added up to the 25 cc. mark. Drops of a dilute solution of ferric chlorid (containing 1 part of ferric chlorid to 9 parts of distilled water) are added, and the mixture again vigorously shaken. If more than 1 per cent of lactic acid be present, the layer of water below is colored an intense greenish yellow. Smaller amounts do not produce a very distinct color change. Strauss' method eliminates sources of error of the ordinary Uffelmann's reaction (mentioned). None of the substances which produce a false reaction (peptones and carbohydrates), nor substances which mask the reaction (hydrochloric acid and phosphoric acid) will be taken up by the ether in any appreciable quantity. The ether employed should be free from alcohol. This method suffices for all practical purposes. It should be remembered that Strauss' test may be negative if the lactic acid is completely combined with the proteins of the gastric juice. Albuminate of lactic acid does not then give up lactic acid to the ether. In such a case, which can occur only when the gastric juice does not react for free acids, it is advisable to shake after hydrochloric acid has been added to the gastric juice up to the 25 cc. mark, and then to perform the Congo-red reaction.

Fig. 207.—Separatory funnel.

Boas' experiments (see p. 462 et seq.), contrary to the old idea, show that the formation of lactic acid is not a part of normal gastric secretion, but is rather due to bacterial fermentations, which are normally prevented by the presence of the hydrochloric acid of the gastric juice. The occurrence of lactic acid in the expressed meals, as demonstrated by Strauss' method, must, therefore, be considered a pathologic condition. This points both to a stagnation of the gastric contents and to the absence or diminution in the amount of the free hydrochloric acid. Only when these factors occur together is opportunity furnished for abundant lactic-acid fermentation. Hence a large quantity of lactic acid is found with *motor insufficiency of the stomach*, more particularly with *stenosis of the pylorus*, and then only when associated with diminished hydrochloric-acid production. As experience shows, this is usually due to carcinoma of the pylorus; hence a certain amount of importance has justly been attached to the demonstration of lactic acid in the stomach-contents as suggesting the diagnosis of carcinoma of the stomach. But the opinion, originally advanced by Boas, that the presence of lactic acid in the gastric juice was pathognomonic of this condition has not been confirmed. *Benign stenosis and gastric insufficiency*, when combined with deficient secretion of hydrochloric acid, has repeatedly furnished a positive test to lactic acid.

¹ Berlin. klin. Woch., 1895, No. 37.

One objection to all the acid fermentation in the stomach Ewald's test-breakfast, always for this reason, substituted a meal, there being no lactic acid seems really unnecessary, as lactic acid which is contained in importance should be attacked by reaction. The advantage of fairly accurately the amount to give a positive reaction from with water (not milk), without

Detection of Volatile Fatty Acids.—*butyric, acetic, or valerianic*—recognized by their characteristic reactions, complicated and hardly practically after the ingestion of food to be attributed to the action of gastric juice, recently more exactly the volatile fatty acids, like lactic acid, and stagnation of the gastric contents occur from what is contained

QUANTITATIVE ANALYSIS.

The quantitative analysis is possible because organic acids, and especially as hydrochloric acid, and because of hydrochloric acid and that what we have already explained the chloric-acid tests. To make the analysis may arrange in the following manner: gastric juice, *i. e.*, those containing free hydrochloric acid and the chlorin-containing compounds for hydrochloric acid, in

1. Acid-reacting constituents
 - (a) Free and combined
 - (b) Organic acids.
 - (c) Acid salts (acid phosphates)
2. Chlorin-containing compounds
 - (d) Free hydrochloric acid
 - (e) Hydrochloric acid combined with organic bases produces no color reaction, but (This is usually called combined acid)
 - (f) Chlorids, neither reacting with organic bases

Titration of the Total Acid.—to determine the total acidity with a $\frac{N}{10}$ sodium hydroxide solution of cubic centimeters of the gastric juice to neutralize a definite volume of the acid follows: As is well known, a normal solution of sodium hydroxide which contains in each liter 40 grams as its molecular weight. A

this by diluting it 10 times. According to the definition, equal volumes of normal solutions neutralize each other: 1 cc. of a $\frac{N}{10}$ NaOH solution neutralizes exactly 0.1 cc. of a normal HCl, etc.

THE PREPARATION OF ACIDIMETRIC NORMAL SOLUTIONS

While formerly it was the custom to use oxalic acid as a standard substance for the preparation of a standard acid, by dissolving 63 gm. of the non-effloresced acid in water, and making up to one liter, more recently, owing to the somewhat inconstant composition of the crystals, pure sodium carbonate (dry) has been used for the purpose of preparing a normal solution. From this a standard decinormal solution of hydrochloric acid is prepared.

Normal Hydrochloric Acid (1000 cc. = 36.458 gm. HCl).—Pure concentrated hydrochloric acid is diluted with water to about 1020 specific gravity, and the resulting solution is titrated against a solution of sodium carbonate. For this purpose 5 gm. of pure sodium bicarbonate are heated in a platinum crucible over a flame for one hour. The heat must be applied gently. The heating is continued until the platinum crucible and its contents no longer lose weight. It is then allowed to stand in a desiccator and finally weighed. From this one weighs out exactly 2 gm., dissolves in 100 cc. water, adds three drops of methyl-orange solution (0.2 in 1000), and titrates with hydrochloric acid until the yellow color of the solution changes to orange. The hydrochloric acid is then diluted with water until 37.7 cc. of the acid are required to neutralize 2 gm. of the sodium carbonate.

Normal Sodium Hydroxid (1000 cc. = 40.058 gm. NaOH).—Fifty gm. of sodium hydroxid are dissolved in cold distilled water, and diluted up to 1000 cc. This solution is titrated against the normal hydrochloric acid, using methyl orange as an indicator, and further diluted until 1 cc. of the alkali exactly neutralizes 1 cc. of the acid.

A decinormal solution is prepared by diluting the normal solution 1 : 10; a centinormal solution, by diluting 1 : 100.

THE TITRATION OF THE GASTRIC CONTENTS

A buret is filled to the zero-point with decinormal sodium hydroxid solution. In a porcelain dish or in a beaker, held over a white sheet of paper, 10 cc. of the filtered gastric juice to be investigated is placed.¹ A few drops [two] of an alcoholic solution [1 per cent.] of phenolphthalein are added. The decinormal solution of sodium hydroxid is allowed to run in slowly until the red color is permanent [and until no deepening of the tint is caused by addition of the alkalis.—Ed.]. The amount of decinormal solution used for neutralization is the expression of the acidity of the gastric contents. The acidity may be expressed in two ways: It may be calculated in terms of a single acid, or, as Jaworski has suggested and a number of writers have followed, in degrees of acidity. Usually the acidity is calculated in terms of free hydrochloric acid. In order to do this it is only necessary to remember that, according to the definition of normal solutions, equal volumes of these neutralize one another: 1 cc. of normal sodium hydroxid therefore neutralizes 1 cc. of normal hydrochloric acid. Normal hydrochloric acid contains in 1 liter one equivalent (i. e., 36.5 gm.) hydrochloric acid; 1 cc. normal hydrochloric acid contains, therefore, 0.0365 gm. hydrochloric acid. This amount of hydrochloric acid corresponds to 1 cc. of normal sodium hydroxid. One cc. of the decinormal sodium hydroxid used corresponds to 0.00365 gm. hydrochloric acid. From these data the calculation of the degree of acidity

¹ Martius has shown that in the quantitative determination of the gastric contents the unfiltered juice should be used, because the acid is divided unequally between the solids and liquids, the solids holding back the greater part of the acid. For practical purposes, however, it is easier to perform the test with the filtered contents. In using the butyrometric method, the filtrate must be used.

in terms of hydrochloric acid is quite decinormal sodium hydroxid to neutralize this corresponds to an amount of 5 cc. of gastric contents of 5 × 0.1825 per cent. This method of calculation does not, indeed, give us the true acidity, but the advantage that it gives us an idea of the acidity of the gastric juice in question in terms of "degrees of acidity" of centimeters of decinormal sodium hydroxid to neutralize 100 cc. of gastric juice. To multiply the number of centimeters of decinormal sodium hydroxid required by 50 gives the degree of acidity. A gastric juice which requires 5 cc. of decinormal sodium hydroxid is therefore, a degree of acidity of 50. The advantage that it expresses exactly the acidity in terms of hydrochloric acid is based on the assumption that the whole of the acidity is due to hydrochloric acid. The calculation to hydrochloric acid gives the degree of acidity in the gastric juice.

Strictly in all titrations of the acidity of gastric juice the facts which Moritz has brought out must be taken into account. This has, however, not been done in clinical practice. The investigation of Voll has shown that the albumose content of the gastric juice in relation to the acidity is of great importance. Volhard has found that considerable differences in the results obtained by the above method to be used in neutralizing the proteins present in the gastric juice, for the same amount of acid as with acids. As phenolphthalein is a rather delicate indicator the end-reaction only takes place when not only the acids, but also of the proteins, are saturated. A comparison of the results which have hitherto been given are too high, and the differences which have been observed between the results obtained by titration and the amount of acid as found by titration with alkalis. In hyperacidity have been found where the titration results are high, on the other hand, high values have been found where the titration results are low. In order to avoid the use of litmus by the drop method (taking care to use a glass rod, and applying it to blue litmus paper) of the second group, of moderate sensitive compounds of alkali with proteins.

Quantitative Estimation of the Acids in the Gastric Juice.—The estimation of the acidity of gastric juice is a very simple chemical operation. The estimation of the amount of hydrochloric acid appears more difficult, because we have to take into account the factors *d*, *e*, and *f* (p. 452). A chloridometer for judging the amount of hydrochloric acid is not available. The total sum of *d* + *e* + *f*, and include *c* if we wish to determine is the sum of hydrochloric acid secreted by the stomach,

Estimation of the Total Hydrochloric Acid in the Gastric Juice (p. 452).—*Sjogvist's Method.*—This depends on the fact that the acids are absolutely free, as well as those which are changed to their corresponding barium salts

mixture be then evaporated to dryness and incinerated, the barium salts of the organic acids will be retransformed to barium carbonate, but the hydrochloric acid will remain fixed as barium chlorid. This can then be isolated from the ash by extraction with water, and then titrated with a solution of potassium bichromate, and the amount of hydrochloric acid be calculated from this. The preformed chlorids in the stomach do not influence the titration, since the latter is concerned only with the barium and not with the chlorid salts.

The steps of Sjöqvist's method are as follows: 10 cc. of gastric juice are slowly evaporated to dryness in a silver platinum dish, with an excess of barium carbonate (free from chlorin). The residue is then kept at a red heat for a few minutes. After cooling, the residue is first digested with 10 cc. of water, and then extracted repeatedly with hot water until the filtered extract amounts to 50 cc.

In order to titrate for barium we add to the solution one-fourth to one-third its volume of alcohol, and 3 to 4 cc. of a solution of 10 gm. of acetic acid and 10 gm. of sodium acetate in 100 cc. of water. These additions facilitate the separation of the barium chromate and prevent the precipitation of calcium chromate from any calcium salt that may be present. An 8.5 per cent. solution of chemically pure potassium bichromate is added from a buret to the solution until the barium is completely precipitated. So-called "tetra paper" (tetra-methyl-paraphenylenediamin paper) will serve to indicate the end of the reaction. Any excess of potassium bichromate will produce a blue color. Every cubic centimeter of bichromate solution which it was necessary to add in order to complete the end-reaction corresponds to 4.05 mg. of hydrochloric acid. Since this reaction is not sharply defined, Sjöqvist has recently improved his method at the expense of simplicity by changing the final titration with bichromate to a much more sharply defined iodine titration. Iodine is quantitatively liberated by adding KI and HCl to the bichromate, and the iodine is determined in the well-known way by titrating with sodium thiosulphate and starch. (See Lehmann's sugar titration, p. 621.) For the technic of this modification we must refer to the original communication in Vol. V of the *Scandinavian Archives of Physiology*, 1895.

Leo's Method.—Leo's method is based on the fact that both free and combined hydrochloric acid are neutralized by calcium carbonate, while acid phosphates and other combinations reacting in the titration with sodium hydroxid show the same acidity after treating with calcium carbonate as before.

Leo first removes the volatile fatty acids by distillation, and the non-volatile fatty acids and the lactic acid by extraction with ether, and then estimates the total acidity of the specimen of gastric juice. In another portion he combines with calcium carbonate both the free hydrochloric acid and that combined with the proteins, and then titrates again. The amount of the acidity which disappears after the addition of calcium carbonate corresponds to the hydrochloric acid present. Calcium chlorid, formed in the neutralization of the hydrochloric acid, necessitates (on account of the probable presence of acid phosphates) especially skilful manipulation when performing the test. If calcium chlorid be absent, the titration of the acid phosphates will be represented by the following formula: $\text{PO}_4\text{H}_2\text{K} + \text{NaOH} = \text{PO}_4\text{HKNa} + \text{H}_2\text{O}$. But if calcium chlorid be present in the solution at the same time, the following formula will represent the titration: $2\text{PO}_4\text{H}_2\text{K} + 4\text{NaOH} + 3\text{CaCl}_2 = (\text{PO}_4)_3\text{Ca}_2 + 2\text{KCl} + 4\text{NaCl} + 4\text{H}_2\text{O}$. In the latter case we need double the quantity of sodium hydroxid for neutralization. Leo adds an excess of calcium chlorid to both specimens before titration, in order to exclude the influence of the calcium chlorid formed by the neutralization with calcium carbonate, when comparing the two titrations. For the details of the technic consult Leo's own communication.¹

Leo's method will also serve the purpose of estimating at the same time the quantity of acid phosphates. It must be pointed out that the principle of Leo's method has been condemned by F. A. Hoffman² and others.

Lütke-Martius' Method.—Lütke-Martius' is one of the simplest methods for the determination of the total amount of hydrochloric acid secreted (free HCl + that combined with proteins).

We first estimate the total amount of chlorin in a specimen of gastric contents³ (see below). This is represented by *a*. Another specimen of the gastric contents is incinerated, the chlorin in the ash estimated, and represented by *b*. The

This method, however, gives incorrect results, because these include the higher fatty acids, which are frequently not completely neutralized by the desired to estimate these higher fatty acids means of the $\frac{N}{10}$ NaOH, must be well shaken and any acidity arising from these fatty acids neutralized with alcoholic $\frac{N}{10}$ NaOH. This neutralized ether extract, in watery solution of the gastric contents, proceeding in this manner we are certain that the organic acids, has been neutralized in which the measure of the previously present acidity. In the Hehner-Maly method is also of acids.

If it be desired to estimate the higher fatty acids in the *unfiltered* gastric contents must be employed (on account of their insolubility in water) butyric acid) on account of their insolubility in gastric contents, and would consequently remain.

Determination of the Free Hydrochloric Acid ("d," p. 452).—Mintz's method of titration with solution to the gastric juice from a burette, with color reaction for free hydrochloric acid with Phloroglucin-vanillin is the most highly recommended by Mintz. It requires but a few drops of the solution, and is not influenced by any organic acid, and the necessity of heating each time the contents is the method tedious. Hence, it has a more convenient method than that described by Minkowski, to 30 drops of phloroglucin-vanillin to be added before titrating, for then, by heating the contents, we can observe the reaction. The test rod should be cooled and washed carefully.

Another reaction, the addition of methyl orange to the contents, and then $\frac{N}{10}$ NaOH solution until the color again to violet, has not given the author much satisfaction, it is so difficult to recognize the final color change. It may be very well recognized with Congo-red solution until the Congo-paper is no longer blue. I recommend this method. The drop method of adding the fluid in a platinum loop to the gastric juice, should not be added to the gastric juice, because it is not necessary. In order to shorten the method a portion of the contents may be used for a rapid approximation, and to be more accurate, necessary may be added, as judged from the color change. However, remember that the titration will not necessarily give the same result as the drop method, of the degrees of delicacy of the indicator. The sensitiveness of Congo-red to organic acids is not high.

Mironescu¹ has shown that the value of the test-measure, especially in the Ewald-Boas test-measure, is not accurate, as the contents are allowed to stand. This is because hydrochloric acid is secreted so gradually that the test-measure is as fast as it is produced. With test-measure

¹ Therap. Monatsch., No.

which are not so easily attacked by the acid, this is not the case. It is then to perform the titration as soon as possible after the contents have been removed from the stomach.

Hoffmann's Method for Determining Free Hydrochloric Acid or the Concentration of Hydrogen Ions from the Reaction Velocity of the Hydrolysis of Methyl Acetate.—This method depends on the fact that hydrogen ions, and free hydrochloric acid, act catalytically in increasing the velocity of many reactions. The reaction which is used is the conversion of methyl acetate into acetic acid and methyl alcohol. The increase in hydrolysis is expressed by the equation:

$$C \cdot D = \log. \text{nat.} \frac{A}{A - x}$$

where D equals the time, C a constant proportional to the concentration of the catalyst, A equals the maximum amount of acetic acid which may be formed from the methyl acetate, and x , the amount of acetic acid which is formed in the time D . From the equation, if the amount of acetic acid which is formed in a certain time, the concentration of hydrogen ions may be calculated. Hoffmann uses two flasks, the one containing a known amount of methyl acetate in a known volume of hydrochloric acid of known strength, and the other the gastric juice with the amount of methyl acetate equal to that in the first flask. From this, since

$$C \cdot D = \log. \text{nat.} \frac{A}{A - x} \quad C_1 \cdot D = \log. \text{nat.} \frac{A}{A - x_1}$$

x and x_1 are the concentrations of the acetic acid formed, C and C_1 , the corresponding constants for the reaction velocity, and the other factors the same as in the first equation. If the time in both reactions be the same, D is eliminated from the equations. If A is known, x and x_1 are known from the titration of the two solutions, therefore, obtains from the equations the values C and C_1 . As the constants C and C_1 are proportional to the strength of the hydrochloric acid, one obtains from C and C_1 the concentration of the hydrochloric acid in the gastric juice. Hoffmann's method is concerned merely with the calculation of the relations of C and C_1 and does not use ordinary logarithms instead of natural ones. It is remarkable for its simplicity and ingenious method which is free from the errors of others, and yet not common. It has far has not been used clinically.

Determination of the Hydrochloric Acid Deficit in a Gastric Contents which does Not Give a Reaction for Free Hydrochloric Acid.—When we speak of a hydrochloric acid deficit we mean the amount of HCl which is added to a definite volume of the stomach-contents in order to obtain the color reactions for free hydrochloric acid. This figure represents, on the one hand, with the amount of proteins and other substances present, and perhaps with the alkaline components of the secretions which combine with the acid; and, on the other hand, with the amount of hydrochloric acid already attached to the proteins. We therefore, call it a deficit in HCl saturation. To determine this deficit, add a $\frac{N}{10}$ HCl solution from a buret to 10 cc. of stomach-contents until the reaction for free hydrochloric acid is obtained in the usual way. This reaction is indicated most accurately by phloroglucin-congo-red.

Determination of the Chlorids of the Gastric Contents.—O. Reissner¹ has pointed out that the estimation of the combined chlorine or of the neutral chlorides has a diagnostic significance in the recognition of gastric carcinoma. He has found a greater increase in the chlorids in this disease than in other affections of the stomach, a fact which is the more striking since the secretion of hydrochloric acid is greatly diminished in gastric cancer. (See p. 464.) Reissner believes

¹ Zeit. f. klin. Med., vol. xlv.

this to be due to the neutralization of the hydrochloric acid secreted at all, by the alkaline juice of the cancerous secretion. If it be desired to determine the directions will be found in the description (p. 455). In carrying out this procedure the method employed. (See p. 456.) By this method Reissner found 100 cc. of gastric contents corresponded to a normal solution; while in carcinoma the chlorids in the solution required 50 to 70 cc. of $\frac{N}{10}$ silver solution.

A gastric ulcer resembles carcinoma in this respect.

Quantitative Determination of the Total Acidity of the Contents.—The amount of total organic acids in the test-breakfast by subtracting the hydrochloric acid from the total acidity, allowing, of course, for the amount of a part in the acidity. Martius considers that during the digestion of the test-breakfast the organic acids are absent, hence, this remainder should equal nil.

The organic acids may also be estimated by the method of Strauss. This gives the acidity due to the organic acids.

Quantitative Estimation of Lactic Acid.—Lutken's method (p. 451) is practical and sufficient for the estimation of the lactic acid in the gastric contents. The reaction (p. 451 et seq.) when a more accurate estimation of iodine required to change the aldehyde form is determined by titration.

If there be required a more accurate quantitative estimation can be obtained by the Strauss modification of the method for the organic acids may be employed with the same diagnostic significance as lactic acid as subordinate.

Practical Utilization and Choice of Methods for the Determination of Acids.—The various methods would seem absolutely essential. We should then, naturally, select Lutken's method to determine the total HCl secreted, Iodine for phosphates, Mintz's for the excess of acid, and, finally, Boas', for the determination of lactic acid. But, as a matter of fact, none of these methods and so many methods would make the examination clogged and tedious for practical use.

Fortunately, in practice it is much simpler. The estimation of acid phosphates is of no practical use. Employ Ewald's test-breakfast. (See p. 455.) Moritz¹ and Martius show that the total acidity is the sum of the organic and hydrochloric acid.

The hydrochloric acids are composed of the free acids with the proteins, and of the free acids as phloroglucin-vanillin. A few examples may be considered) even a simple acidity test furnishes considerable information about the gastric contents provided the qualitative tests have been applied.

Let us assume a case where the test-breakfast is negative. The total acidity is found to be 1 cent. in terms of HCl. We may then assume that of this high acidity is due to free organic acids.

¹ Deut. med. Woch., 1893, N. 1.

² Deut. Arch. f. klin. Med., 1893, N. 1.

secretion is slight. If the lactic-acid test be very marked, if butyric or acetic be strong, and if the stomach-contents abundance of bacteria, this assumption is practically proved. If the hydrochloric-acid reaction be very pronounced, the reaction very faint or absent, and the acidity very high, in all probability there is an abnormal or excessive secretion of free HCl. If the acidity be relatively low and the hydrochloric-acid reaction possible, the probability is still greater that the acidity depends largely upon free hydrochloric acid. The titration for the total acidity is valuable, independent of the tests for free hydrochloric acid, for it indicates the maximum limit of HCl which is possible. For example: If the acidity be 0.08 per cent. (calculated as HCl), we are sure that the amount of free hydrochloric acid is not more than 0.08 per cent. anyway; and that it is considerably diminished.

The excess or deficit of acid (see p. 458 et seq.) is easily estimated and gives us an important insight into the gastric chemistry. Some authorities, as is well known, consider that in the determination of hydrochloric acid—the free hydrochloric acid—is the important part to be determined, because in artificial digestion that is the only part which is active. Others, on the contrary, consider that the free HCl can be considered as being, so to speak, useless, while the hydrochloric acid which is combined with the proteins is the important part, because it is accomplishing digestion in the stomach. Both are probably true in a measure. The combined acid is doing the work, but the presence of a moderate excess is a favorable sign. It shows that there is enough to saturate the proteins and still leave more ready for use to be digested. The excess also aids in the antiseptic action in the stomach. But at the same time the hydrochloric acid cannot be considered to measure an actual deficiency for the purpose of diagnosis. On the other hand, the author wishes to warn against the over-estimation of the value of finding free hydrochloric acid. Certain authorities believe that the presence of the acid in the gastric contents is an important factor in the pathology of the stomach. Both here and in the discussion of the value of the desmold reaction the author wishes to point out that the finding of free hydrochloric acid after the meal, one which contains a minimal amount of food, and which, therefore, not be compared to those after an ordinary meal. It is often repeatedly observed after siphonage following a full meal. The amount of free hydrochloric acid to be found in the siphonage after the meal with healthy individuals is often very different. Sometimes free hydrochloric acid is present, sometimes not, according to the amount of digestion at the time of siphonage. With a patient with only feeble digestive powers, the boundary between the presence or absence of free hydrochloric acid may shift from one examination to another. Moreover, it has been shown in recent investigations that peptic digestion may take place in the absence of free hydrochloric acid, provided the total acidity be sufficient. According to A. Müller,¹ the dog can digest completely in the absence of free hydrochloric acid.

The author also points out the relatively slight importance of free hydrochloric acid, and shows that with sufficient total acidity, peptic digestion takes place, even when the deficit in free hydrochloric acid is considerable.

the mixture amount to 0.16 per cent., and Cohn puts it even as 0.07 per cent. Schüle¹ has contributed valuable facts in to the normal course of the acidity of the gastric juice and individual components with different diets. He pictures the following (Fig. 208) to show the relations of the acidities after the of an Ewald test-breakfast.

Course of the acidity of the gastric juice after a test-breakfast of 300 gm. of tea and 50 gm. of milk-bread (after A. Schüle).

note his observations upon healthy persons in the following:
 1. The values of the free as well as of the combined HCl and of the total often differ considerably in the same individual and in different people, for any demonstrable cause. 2. The maximum of free HCl varies between 0.07 and 0.2 per cent.; the combined acids, between 0.012 and 0.11 per cent. The maximum of the total acidity lies, in round figures, between 30 (0.11 per cent. HCl) and 70 (0.26 per cent. HCl) at the height of digestion. 3. The height of the maximum occurs sixty minutes after an Ewald test-breakfast, varying in individuals from forty-five to seventy-five minutes. 4. The upper limits of these values must be regarded as pathologic for many individuals with sensitive gastric membranes."

Diagnostic Notes upon Acid Contents of the Gastric Juice

As we do not attempt to draw conclusions in regard to the volume of secretion from the percentage of acidity (see p. 479), experience teaches us that normal hydrochloric acid secretion is present:

Very often in gastric ulcers, and in the pyloric stenosis due to a healed gastric ulcer.

In some of the gastric neuroses.

In simple atony of the stomach.

The hydrochloric acid secretion is found to be increased:²

In the majority of the cases of gastric ulcer.

In motor insufficiency of the stomach (Schreiber) with maintained secretion of acid.

¹ *f. klin. Med.*, 1895, vol. xxviii.

² The free hydrochloric acid after an Ewald test-breakfast exceed 0.2 per cent., the total acidity amount to more than about 70 (0.26 per cent. HCl), we may regard as an increased secretion. Pathologically, total acidity as high as 0.8 per cent. has been observed, due chiefly to HCl, but values over 0.35 per cent. are rare.

 - (10) In chlorin hunger⁴ after the prolonged use of alkalis.
 - (11) Not seldom in diabetes mellitus.
- (d) Free hydrochloric acid is absent in the gastric juice:
 - (1) In severe febrile, especially infectious diseases.
 - (2) In carcinoma of the stomach.
 - (3) In atrophic gastric catarrh.
 - (4) In pernicious anemia. Here per total acidity there is a defect in the secretion of hydrochloric acid (pernicious anemia) in consequence of a defect in the secretion of hydrochloric acid.

In reality, numerous deviations are of course possible, and the above scheme is grouped in the above scheme.

We are justified in attaching great weight to a negative result in the color test for hydrochloric acid, especially if this HCl absence can be felt. Nevertheless, the presence of free hydrochloric acid is not a certain diagnosis of a carcinoma. One case was observed in this respect. For months he found a normal test-breakfast, although the patient presented pylorus with marked nocturnal retention of food. Other writers have reported similar observations. The conditions cited in groups c and d are frequently accepted.

¹ See p. 446 for the amount of secretion in healthy individuals.

² The most important differential diagnosis is between hypersecretion (gastrosuccorhea) and cases where no juice occurs, due to motor insufficiency, with the condition of the fasting stomach in the morning after the evening before. If it, then, the condition is one of true hyperacidity.

³ There is really no sharp boundary between the percentage of acid contained in the gastric juice and the volume of the gastric juice secretion. Hyperacidity and hypersecretion result from a motor insufficiency (stagnation of the gastric juice).

⁴ The more exact quantitative methods for the determination of hydrochloric acid, e.g., Lütke-Martius, would show that the amount of hydrochloric acid was secreted. Yet the color test for free hydrochloric acid is pressed and the gastric juice then give a negative result.

on for free HCl, so that an absence of free HCl can hardly be claimed as of gastric carcinoma.

considerable amount of organic acids, especially of lactic acid, occurs hydrochloric acid is absent and when, at the same time, motor insufficiency, especially when the latter depends upon some stenosis of the pylorus. reason that a considerable amount of lactic acid in the gastric contents suggests a carcinoma.

of the Digestive Power of the Gastric Juice ; Examination for Pepsin

digestive power of the filtered stomach-contents from the ex-st-breakfast depends, on the one hand, upon the amount of retained, and, on the other hand, upon the amount of free acid, especially free hydrochloric acid. Negatively, the digestive the gastric juice is influenced by the presence of substances digestion. Artificial digestion is the only means at our com-estimate the amount of pepsin. This furnishes also indirect of the amount of acid contained in the gastric juice.

tificial digestion we usually employ fibrin stained with carmin), or disks of coagulated egg-albumen.

rin is best prepared by beating freshly drawn ox-blood. The stringy washed in running water until decolorized, and then cut into small uniform size, which are then placed in alcohol for several days. They transferred for one to two days into a $\frac{1}{4}$ to $\frac{1}{2}$ per cent. ammoniacal solution of which should contain as little excess of ammonia as possible and kept cool are thoroughly stained, washed in water until the wash-water is no longer all squeezed, and then preserved in glycerin. Before being used they are fully washed in water to free them of glycerin.

egg-albumen disks are prepared by boiling an egg hard,¹ and then with a punching out the white cylinders of about 5 mm. diameter. These are sectioned with a razor into small disks of 1 mm. thickness, preserved and also washed off before using.

the digestive test a few bits of fibrin or some egg-albumen disks to a test-tube with a measured quantity of the gastric con- the tube then set in an incubator. The digestion of the releases the carmin and becomes evident from the red color of the the digestion of the egg-albumen always progresses much more it shows itself first in the rounding of the edges of the disk, gradually by complete solution.

following methods are to be recommended for a more accurate ve examination:

Schlag's² Method for Estimating Pepsin.—Ten cc. of an approxi- cent. filtered solution of egg-albumen³ in 0.4 per cent. HCl are poured es. To one 5 cc. of gastric contents are added, and to the other 5 cc. water. They are both set in the incubator. An hour later the albumin es is estimated volumetrically according to Esbach's method (p. 615 the difference between the precipitate of albumin in the two tubes is e amount of albumin which has been digested, and forms, therefore, f the peptic activity of the gastric juice The square root of the amount

g should be boiled only long enough to coagulate the egg-albumen com- ewise it becomes too difficult to digest. The necessary boiling period nd experimentally.

at. klin. Rundschau, 1895, vol. viii, No. 39.

egg-albumen contains about 13 per cent. of dry protein and should there- ed about 13 times in order to make approximately a 1 per cent. solution en.

of pepsin is proportional to the quantity of Borissow,² and Lincosier.³ The objection is not very accurate, and that the albumin error in regard to the precipitation of the down so finely divided and settle with so not influence the amount of the sediment is sufficiently accurate for practical utility in stomach-contents. It would be better, however, for the reasons given in the description of L

Mett's⁴ Method of Pepsin Determination. To 2 mm. in diameter and 20 to 30 cm. in length portion of fresh egg-albumen. In order to obtain albumen, the whites of several eggs should be added to the fluid portion of the mixture employed. The bread-crumbs and placed horizontally in a dish of the albumin quickly. At the end of five minutes and their ends plunged into melted paraffin. The ends of these capillary tubes may be prepared by the method employed, it should be noted that the cylinder of the walls of the tube and have not dried out and be unfit for use. At first the capillary tubes are gradually disappear, and in two days they are reduced into lengths of about 2 cm. with a file, and 5 cc. of the acidulated gastric contents, the digestion is complete. The manner in which the digesting mixture is prepared will be subsequently stated. Digestion is complete; it is manifested by the fact that the ends of the tubes, the disappearance of the

According to Nirenstein and Schiff,⁵ the amount of pepsin digested by any gastric juice is proportional to the square of the diameter of the capillary tube. If the diameter of the digested cylinder does not exceed 7 mm., the amount of pepsin digested cylinder exceed 7 mm., however, the amount of pepsin digested time, since the digestion beyond this point is the result of the difficulty of the diffusion of the digesting fluid. To obtain a correct quantitative estimation of the gastric contents we must consequently determine the amount of pepsin done by preparing the digesting mixture in a known volume and measuring the mass of albumin dissolved. The amount of pepsin may be roughly estimated macroscopically with a microscope provided with an objective and a micrometer. If employed, their four ends furnish four determinations which may be obtained.

For solutions of pure pepsin, Schütz⁶ has found that the quantities of pepsin in digesting mixtures of hydrochloric acid are proportional to the square of the length in the same time. Borissow has confirmed the law of Schütz, so that in this connection the length of the digested cylinder of albumin is proportional to the concentration of the solution. From the studies of Schütz it is true only for the less concentrated pepsin in the digesting fluid be so large that more than twenty-four hours, the law of Schütz does not hold. The quantity of pepsin in any gastric juice by Mett's method is determined that the digestion length will not exceed 3 cm. already given two reasons which make it impossible to determine the amount of the contained

⁶ Schütz and Huppert have found that the amount of pepsin is proportional to the square root of the time (p. 468.)

tant reason for such dilution, to which the author referred in a previous edition of this book, and which has recently been more critically discussed by Nirenstein and Schiff, is that the gastric juice, as obtained from the patient by filtering the gastric contents after a test-breakfast, always contains an uncertain quantity of substances which inhibit pepsin digestion. These inhibiting substances are the products of the peptic digestion itself; Nirenstein and Schiff state that they are particularly the dissolved carbohydrates and also sodium chlorid. Gastric juices with diminished amounts of hydrochloric acid, on account of the large quantities of carbohydrates which they contain, are the richest in such inhibiting substances. The important rôle played by these inhibiting substances is shown by the fact that, if Mett's method be carried out with different slight dilutions of the same gastric juice, the relative pepsin values, as obtained by applying Schütz's law to the digestion lengths, never agree with the relative amounts of pepsin as calculated from the dilution. As a matter of fact, it will be found that if the gastric juice be diluted to two or three times its volume, a higher digestive value will frequently be obtained than if the undiluted juice be employed. This is evidently due to the fact that in such a dilution the diminished amount of pepsin is more than compensated for by the weakening of the activity of these inhibiting substances. The presence of these substances consequently gives rise to conditions beyond computation, which make it impossible to arrive at accurate conclusions if the pepsin value be calculated from the pure gastric juice.

It is apparent that the way to avoid this difficulty is to eliminate this inhibitory action by diluting the gastric juice. In a previous edition of this book, having this end in view, the author recommended a tenfold dilution of the total gastric juice in diluted hydrochloric acid. Nirenstein and Schiff, however, have shown that it is better to carry the dilution still further. They recommend a sixteenfold dilution with $\frac{N}{20}$ hydrochloric acid (= 0.18 per cent. HCl), and state that Schütz's law obtains with this and all further dilutions. The latter requisite is absolutely necessary if we wish to have a relative expression for the quantity of pepsin as estimated from the digestion length. This marked dilution also decreases the amount of pepsin in the mixture, so that the digestion length is kept within the limits of Schütz's law (3.9 mm. in twenty-four hours). The author must, nevertheless, observe that this is not always the case with a very active gastric juice, so that if the digestion length exceeds 3.9 mm. with a sixteenfold dilution, it becomes necessary to repeat the pepsin test with a dilution of 1 : 32.

According to Nirenstein and Schiff, the method of Mett will consequently be carried out in the following manner if exact quantitative results are to be obtained: 1 cc. of the filtered gastric contents is diluted with 16 cc. of $\frac{N}{20}$ HCl (= 0.18 per cent. HCl). Two Mett's tubes are then laid in this mixture which is placed in the incubator. At the end of twenty-four hours the digestion lengths are read and the mean digestion length calculated. The square of this digestion length is the measure for the relative amount of pepsin in the sixteenfold diluted gastric juice, and this number, multiplied by 16, gives the relative amount of pepsin in the undiluted gastric juice. In those cases in which the length of the digested cylinder of albumin exceeds 3.9 mm. in length, in spite of the sixteenfold dilution, the estimation must be repeated with a dilution of 1 : 32. By squaring the digestion length as before, and multiplying this quantity by 32, the relative amount of pepsin in the undiluted gastric juice will be obtained. In order to facilitate matters it is better to perform several tests at the same time with dilutions of 1 : 16, 1 : 32 and 1 : 64. One has then the opportunity of observing whether the results conform with the law of ferment action. It is clear that in this method of estimation the unit of the relative amount of pepsin will be that quantity of pepsin by which 1 mm. of albumin in a Mett's tube will be digested in twenty-four hours with an acidity of 0.18 per cent. free hydrochloric acid. In this estimation we do not consider the absolute quantity of the pepsin, but simply the degree of its concentration, for the result of Mett's method is the same whether large or small quantities of the digesting mixture be employed; at least for quantities above the 16 cc. above recommended. By employing this method Nirenstein and Schiff have found striking differences between individual gastric secretions, which vary between 0 and 256 pepsin units. A content of 0 to 70 is to be considered low; 70 to 150, average, and 150 to 256, high. The pepsin concentration is consequently entirely independent of the amount of acid in the gastric juice, as we might expect from the fact that physiologists have demonstrated a different localization for the formation of pepsin and hydrochloric acid in the gastric glands.

Against the Mett estimation has been objected that the measurements of the

digested albumin are so small that the error is so magnified that it plays much too great a part. A more serious objection is that of Arrhenius. An investigator has shown that when alkaloids are allowed to diffuse into a capillary tube held for diffusion, so that with a solution of diffusion takes place twice as rapidly as follows that the results of Nirenstein and are dependent on the rate of diffusion. If diffusion were the predominant factor, the variations of pepsin, which is not the case. The concentrations, an inhibition. With Mett's method one is unable to show that the Schütz law holds for pepsin units, as the results, taking into account, are in agreement with a simple proportion between concentration of the solution.

Volhard's Method for Estimating Pepsin. The fact that casein, dissolved in hydrochloric acid, is completely precipitated by sodium carbonate. To act on a solution of casein at 40°, the less will be the precipitate produced. To have estimated the amount of casein left in solution after action. The technical difficulty of titrating the precipitate is avoided by Volhard, by making use of the fact that an amount of hydrochloric acid is precipitated, while a proportional amount of sodium carbonate, estimates the acidity after precipitation. He compares with this the acidity of a partial solution, the increase in acidity of the latter. Volhard finds proof for this in that the amount of precipitate is proportional to the square root of the amount of acid. If, therefore, one wishes to estimate the amount of pepsin, one allows a definite volume of the gastric juice to act on a known HCl casein solution at 40° C., and after a definite time, and titrates the solution with sodium sulphate. The same casein solution. The difference in the acidity of the two solutions gives the relative amount of pepsin contained in the gastric juice.

As, however, the ferment law is valid, one can determine the amount of pepsin from a series of tests with different concentrations of gastric juice, which correspond to the ferment law. For example, if one uses only those tests can be used when the first 4 cc., and the third 9 cc., and the digestive increase in acidity are in the ratios of 1 : 2 : 3. If unequal, one must, according to Volhard and Huppert, take into consideration that the amount of precipitate is proportional to the square root of the ferment coefficient, and that the increases in acidity behave according to the ferment or amount of gastric juice, $t = \sqrt{a}$, the relation between increase in acidity and amount of pepsin.

Technic.—Casein solution. 100 gm. of casein is mixed with 100 cc. of distilled water and 10 cc. of sodium hydroxid are added, and diluted to 2000 cc. The casein is completely dissolved, and the solution is cooled, and a few cubic centimeters of to destroy any proteolytic ferment which may be present.

Volhard uses long-necked digestion flasks of 400 cc.

The test is made in the following way. A definite amount of acid are measured into three digestion flasks. To the contents of each flask are added a definite amount of casein solution. The mixture is shaken. No precipitation

a but varying amount of the gastric juice (see later), best after the casein is warmed on the water-bath to 40°. The whole is then diluted to 300 cc. The mixture is then digested for an hour in a water-bath at 40°. In order to stop digestion it is necessary to add only 100 cc. of 20 per cent. sodium sulphate (up to 100 cc. mark). This precipitates the undigested casein, and the hydrochloric acid which is in the soluble digested portion remains in the solution.

The acidity of 100 or 200 cc. of the filtrate is estimated with decinormal sodium hydroxide. The total acidity of the filtrate from an undigested test is determined once. This is subtracted from the acidity of the digestion tests, in order to determine the increase in acidity due to digestion. This acidity is, therefore, a measure of digestive activity. The initial acidity of the gastric juice must naturally be determined from that of the digestion mixture. In spite of what has been said on Volhard's use of phenolphthalein as an indicator. In case of normal or hyper-acid gastric juice Volhard employs 0.2, 0.8, 1.8 cc., or when sufficient gastric juice is to be had, 3.6 cc. With juices containing no acid or of feeble acidity, 1.0, 4.0, 9.0, 16.0, and 18.0 cc. With these proportions it is altogether probable that at least one of the tests of each group will fall within the limits of the law of ferment action. Schapiro¹ has made determinations in the author's laboratory with gastric contents of high ferment activity and much acid. The results are best with 0.1 and 0.2 cc. of gastric juice (0.1, 0.4, and 0.9 etc. with weak gastric contents, of low acidity). With additions of 5 cc. and more (4.9, 6.4, 8.1, relations of 0.1×7^2 , 0.1×8^2 , 0.1×9^2) or 5.0, 7.2, and 9.8 (0.2×5^2 , 0.2×6^2 , 0.2×7^2).

In order to find out definitely what are the quantities of gastric juice which are necessary, Volhard says that one should use 10 times the smallest amount which gives a positive result in the determination of the coagulating ferment. For example, if the coagulation is in dilution II (1 : 100), 0.9, 0.8, 0.7, up to 0.4 cc. are positive (coagulation), in dilution II (1 : 100), 0.3, 0.2, 0.1 cc. negative (no coagulation), the smallest amount is 0.4 cc. of dilution II = 0.004 cc. In this case, therefore, for the tests 0.04, 0.16, and 0.36 cc. of gastric juice (relations of 1, 4, 9) in dilution II of undiluted unneutralized gastric juice. The gastric juice is measured with a pipet which allows the measurement of 0.01 cc. The values for pepsin activity fall pretty closely within the laws for ferment action. With achylic or atrophic gastric juices there is often not enough juice with which to perform the tests. In this case we must be content with one test.

If a value within the ferment law has been found, the following calculation, according to Volhard, can be made.

We assume as the ferment unit that amount of ferment which gives in one hour of digestion an increase of 1.0 cc. of decinormal alkali for titration, and designate the increase in acidity, then, according to the Schütz-Huppert rule, by x . a = cc. of gastric juice which contains x ferment units per cubic centimeter—

$$a = \sqrt{nxl}.$$

$$\sqrt{x} = \frac{a}{\sqrt{nl}}$$

$$x = \frac{a^2}{nl} = \text{number of pepsin units in 1 cc. of the gastric juice.}$$

The only questionable if it be right to assume that, in the above formula, the reaction should be influenced by the square root, or, in other words, whether the reaction velocity for peptic digestion is a function of a square root. This so-called time law for pepsin (x) has not been perfectly proved. (See the Carmin Method.)

Volhard's has the advantage over Mett's method that with weak gastric juices results will be obtained when no digestion can be observed with Mett's tubes.

Grützner's Carmin-fibrin Method for the Quantitative Estimation of Pepsin. This method, which was proposed in 1874 by Grützner for the determination of pepsin, and which was for a time quite superseded by other methods, is again attracting attention from clinicians since Grützner and Korn² have again pointed out the simplicity of the method, and have shown that by it the pepsin ferment can be worked out more easily than with any other method. The principle of the carmin fibrin is that one allows a digestive juice to act on a fibrin stained with carmin for a certain length of time, and estimates colorimetrically the amount of carmin set free, by comparing it with carmin solutions of a definite concentration.

Schapiro, Volhard's Method for Estimating Pepsin. Inaug. Diss., Bern, 1902.

Grützner's Arch., 1874, vol. viii, p. 542, and Habilitationsschrift, Breslau, 1875.

Korn, Quantitative Pepsin Estimation, Inaug. Diss., Tübingen, 1902.

The intensity of the color is proportional to the amount of fibrin digested, the degree of the digestion. The number of the comparison mixture gives the amount of digestion in units. Therefore, by this method the determination is more exact than by any other. Five tests are made in which, as nearly as possible, the same amount of stomach contents is used, the same amount of stomach contents exceed 0.5 gm. The amount of fibrin is to be more exact, is weighed after being present, of fibrin are added:

The fibrin carmin is prepared as shown in the following colors. Ten different solutions of carmin

The first	contains	0.1 cc.	1 per cent
The second	"	0.2 "	1 "
The third	"	0.3 "	1 "
The fourth	"	0.4 "	1 "
The fifth	"	0.5 "	1 "
The sixth	"	0.6 "	1 "
The seventh	"	0.7 "	1 "
The eighth	"	0.8 "	1 "
The ninth	"	0.9 "	1 "
The tenth	"	1.0 "	1 "

The Digestion Test —As the intensity of the color is proportional to the amount of fibrin digested, the degree of the digestion. The number of the comparison mixture gives the amount of digestion in units. Therefore, by this method the determination is more exact than by any other. Five tests are made in which, as nearly as possible, the same amount of stomach contents is used, the same amount of stomach contents exceed 0.5 gm. The amount of fibrin is to be more exact, is weighed after being present, of fibrin are added:

In test-tube 1	9.95 cc.	0.3 per cent
" " 2	9.90 cc.	0.3 "
" " 3	9.80 cc.	0.3 "
" " 4	9.55 cc.	0.3 "
" " 5	10.00 cc.	0.3 "

The test-tubes are allowed to remain undisturbed and are shaken during this time every five minutes with the scale of colors. As the relative intensity of the color is proportional to the amount of ferment, one has an estimate of the ferment laws with regard to the factors of digestion of ferment. From Korn's investigation, it may be estimated in a five-minute test. The amount of pepsin in mixtures 1, 3, and 4 is 1, 4, and 16, respectively. The relative amounts of ferment are as 1, 4, and 16, respectively. As a rule, must be estimated, the limits of the law of ferments, the content of the law. Supposing that the mixture 1:4 in five minutes mixture 1 has a color intensity of II, and 4, to III. One takes any one of the test-tubes of gastric juice in 10 cc. — a dilution of capacity of II. If we assume as the unit of ferment free in five minutes as 1 (the expression for the square root of the pepsin concentration is proportional to the digestive capacity), such a mixture contains $2 \times \sqrt{50}$ peptic units. If the ferment is 1, the number is to be divided by 2, as it has 100 units. In titrations the amount of digestion is proportional to the square root of this factor. Another method of unit

The Grützner method is one of the best. The only disadvantage is that the color may be avoided by preparing them fresh. Grützner has endeavored to overcome this difficulty by preparing a solution of sodium rosanilin trisulphonate (Merck) prepared by mixing with 50 cc. glycerin, 2.5 cc. sodium rosanilin trisulphonate and 2.5 cc. picric acid. After finding that a solution of color as the carmin solution x, and one has

min by the addition of the red or yellow components, standard solutions are prepared by using the original solution as solution 10 and adding to 10 test-tubes 1, 2, 3, 4, 5, 6, 7, 8, 9, cc. of the standard solution and diluting to 10 cc. with glycerin. These solutions are stable. Another method which the author has found useful is to stain the fibrin with Berlin blue instead of with carmin. The Berlin-blue solutions, as far as the author has been able to ascertain, are stable. As the so-called Berlin blue is not, strictly speaking, soluble in water, the fibrin must be so stained that the color is formed in the fibrin itself. In order to do this the fibrin is first immersed in a solution of potassium ferrocyanid, and subsequently in a solution of ferric chlorid. The solutions must be very dilute, for stronger solutions impair the digestibility of the fibrin. It has also been found useful to perform the test in the following way: Fibrin which has been preserved in glycerin, and which has been exposed neither to heat nor to the action of alcohol, is freed from glycerin by soaking in water and just covered with a 1 per cent. solution of potassium ferrocyanid, and allowed to stand for eight hours. The supernatant fluid is then poured off and measured. An equal volume of ferric chlorid solution of the following composition is then poured on, and the fibrin and solution transferred to a porcelain mortar, and well rubbed up until the protein is homogeneously blue in color. The dilute ferric chlorid is prepared by adding to 10 cc. of water 1 cc. of liquor ferri sesquichlorati diluted six times. The stained fibrin is well washed with water to remove excess of color and small particles of fibrin. The protein is then placed in glycerin and preserved. Fibrin obtained in this way does not lose its color or its capacity for digestion. The standard solutions for the comparison of the color are so prepared that the darkest solution (x) is made. This is done by dissolving Berlinblau (Grübler) to the desired tint in decinormal oxalic acid solution, and making other solutions containing 9, 8, 7, 6, 5, 4, 3, 2, 1, cc. of this solution to 10 cc. with decinormal oxalic acid solution. The solutions are stable so far as the author has been able to observe, for at least some months, provided they are kept in sealed glass tubes and protected from light.

Jacoby's Method for Estimating Pepsin.¹—This method depends on the fact that a solution of ricin in 1 per cent. sodium chlorid, in consequence of the protein contained in it, is not clear, but with the addition of hydrochloric acid and pepsin the opalescence appears. The amount of gastric juice is determined which is sufficient to clarify such a ricin solution of a definite concentration. The details of the method will be found in a paper by Solms.² Ricin is now a comparatively inexpensive article of commerce. The "Vereinigte Chemische Werken," Charlottenburg, Salzufer 16, sell it with directions for performing the test. Apparently Schütz's law does not hold in the ricin test. This is due to the fact that we are here dealing with the minimum digestive capacity in which inhibitory factors probably do not play an important part.

Fuld's Method for Estimating Pepsin.³—This method is based on a principle similar to that of Jacoby. Fuld prepares a solution of edestin in hydrochloric acid, and determines the amount of gastric juice necessary for the complete digestion of the edestin. When the protein is completely digested, no ring of protein is formed by placing ammonia solution on top of the digestion mixture. In this method Schütz's law is not followed. It is a limit method, and the proportion between digestive action and amount of pepsin is a direct one.

Gross' Method for Estimating Pepsin.⁴—This method is similar to those of Jacoby and Fuld. A very dilute solution of casein in hydrochloric acid is used. The concentration employed is 0.1 per cent. This is prepared by heating 1 gm. of casein with 16 cc. of a 5 per cent. solution of hydrochloric acid (sp. gr., 1.114) made up to a 1000 cc. with water until the casein is dissolved. A number of test-tubes are filled with this solution, previously warmed to body temperature, and increasing amounts of gastric juice added. These remain at this temperature for a certain time, and the casein is precipitated by a solution of sodium acetate. The limit is determined when no precipitate is produced by adding this solution.

Schorer's Refractometric Method.⁵—G. Schorer has worked out a method in the author's clinic, using the Pulfrich immersion refractometer. The details will be found in the original paper. The method is based on the experiments of Obermeyer and Pick⁶ who showed that during digestion of egg-albumen, the refractive index is not altered. The egg-albumen solution is prepared of a concentration of

0.62 per cent., and of this, 40 cc. are mixed and 0.1 cc. of the gastric juice. The mixture of this mixture are used for a refractometric determination are digested at 40° in a thermostat for twenty minutes and are then mixed with 1 or 2 drops of azolitmin solution neutralized with sodium hydroxid. Then a small amount of the solution must now be distilled. The color of the solution must now be distilled. acid albumin is produced. The mixture is then boiled. If the mixture lose its red color during boiling, a few drops of the solution be added to restore it. On cooling the solution is read with the refractometer. The difference between the readings before and after digestion gives a measure of the amount of pepsin. expressed either in units of pepsin or in units of activity. can be obtained only when more than one test is made. the limits of the law of ferments.

CRITICISM OF THE CLINICAL METHODS WITH SUGGESTIONS FOR

The newer methods for the estimation of the extent the conditions for obtaining an accurate measurement of gastric juice in pepsin. This is, however, called ferment law is a quantitative one. The methods are so designed that the resulting factors. With regard to the action of pepsin digests proteins, the views of chemists are in accordance. Some assume that the reaction is a straight line while other believe there is a strict proportion of ferment and the amount of digestion. The action representing the action of pepsin is a straight line. The action is rapid at first, and then rises slowly. In the beginning the reaction follows a straight line but later there is a quadratic relation between the concentration of the pepsin. In the beginning apparently no mathematical formula can be applied to the reaction. If, however, the assumption is made that the minimal action of pepsin the simple reaction, as in Jacoby's and Gross' methods, are used for clinical purposes to the author that it might be better to use a quantitative estimation of pepsin for clinical purposes. one's attention to an examination of the reaction with regard to its digestive capacity. The method for clinical purposes is not to know what amount of gastric juice, but to ascertain in and how much the gastric juice exercises its function. A gastric juice will not be of any value to the patient if the gastric juices, either from products of digestion or from the work. And, conversely, it is not necessary that a very great ferment activity to perform its function if the inhibitory factors are absent. Under the conditions in the stomach, we must examine the reaction and not rely on the determinations of pepsin. The method is a modification of the carmin test. The author in the earlier editions of this book was not aimed at, but undiluted gastric juice of low acidity, it is wise to make a second

st up to 0.2 per cent. hydrochloric acid. The amount of gastric l the fibrin must be the same in both tests. In order not to in- e amount of the gastric juice unduly by the addition of acid, r must be added in a concentrated form, only the few drops y to bring the concentration of the acid up to the desired amount. st be determined beforehand by a preliminary titration. Two ests can be made, in which equal amounts of boiled and unboiled used, and also equal volumes of gastric juice and water. In es also, the total volume of the mixture, the acidity, and the of fibrin must be alike. The object of these tests is to obtain ion through the addition of water, and the destruction of the regarding the presence of inhibitory factors. This information ortance because such inhibitions may be the cause of gastric nces, due to the retention in the stomach of the products of ; and this may be relieved by increasing the motility of the This method, therefore, gives results regarding digestion as such, of the amount of pepsin contained in the gastric juice. The as of the experiments are also those which determine the pres- nhibitory factors.

principle of investigating the undiluted gastric juice may also ed to other methods than the carmin test, *e. g.*, the refracto- method or the Mett tube method.

Technical Value of the Quantitative Methods for the Estimation of Pepsin

Examination of the Gastric Juice for Rennin and Rennin Zymogen

l gastric juice contains, besides hydrochloric acid and pepsin, rennin fer- rennin zymogen as additional secretory products of the mucous mem- man and the pig the ferment is parachymosin, which is different in prop- a the ferment chymosin found in the stomach of the calf. As we well ain possesses the property of coagulating milk, independently of the help Rennin zymogen, inactive in itself, is converted into rennin by acids. rapidly destroyed by alkalis, but the zymogen is much more resistant to

monstrate rennin, 3 to 5 drops of gastric juice are added to 5 to 10 cc. ncooked neutral or amphoteric milk, and the mixture is placed in an

If the rennin be present in normal amounts, curdling should take om ten to fifteen minutes (Leo) In this process the slight amount of d in the gastric juice will cause no precipitation If the curdling take slowly, it is questionable whether it is due to the action of the rennin ormation of lactic acid, and so, to be exact, the reaction of the mixture

process, in which insoluble casein is formed from the caseinogen of the milk ultaneous action of rennin ferment and calcium salts, must not be con- ith the precipitation of unchanged caseinogen by acids (the curdling of etic-acid fermentation).

is taken before and after curdling has taken place. It occurred only when curdling occurs with

Regarding the presence and the tests for pepsin, many statements of question are to be detected by making the gastric juice slide with an equal volume of unboiled milk. A dense coagulum will be formed in eleven minutes, exclusive, for Fuld has shown that the reaction is due to salts of calcium, hence Boas' test depends on the absence of enzyme which are present being calcium salts.

Blum and Fuld have observed that the gastric contents containing no hydrochloric acid, pepsinogen is transformed into the ferment. If no pepsinogen, one must make the juice acid with hydrochloric acid, and then test its coagulating properties, the acid test. A control test is made with the gastric juice and hydrochloric acid.

An approximate estimation of the amount of pepsin made, according to Boas, by not taking into account coagulation, but by determining the least amount necessary to coagulate a definite amount of milk, and the juice is added to equal volumes of milk, and the time of coagulation. In normal gastric contents, the reaction is sufficient, while in severe cases of insufficiency it is 1 : 10.

The significance of these tests is similar to that of the gastric contents the secretion of pepsin and is assumed, following Hammarsten's observations, to be identical. The approximate estimation of the amount of pepsin, that it is easier to observe than that of pepsin, that it is easier to observe only in severe pathologic conditions. According to Boas, the limit of dilution is of the order of 1 : 1000. The absence of the ferment is found only in carcinoma, and in a group of cases of pernicious anemia.

Quantitative Estimations of the Coagulating Power of the Gastric Juice (Boas and Fuld).—A preliminary test is made by adding 2 cc. of the filtered gastric juice, and increasing the dilution until no coagulation is observed. The tubes are allowed to remain at 15° C. for two hours. If no coagulation is observed, the mixture is heated to 37° for five minutes. The more effective the coagulation, the greater the amount of pepsin. Fuld expresses this in terms of the dilution at which coagulation occurs. A dilution of 1 : 8000 has a relative value of the gastric juice may be very high. In severe cases, no ferment action is found.

Quantitative Estimation of Rennin.—Milk is mixed with a few drops of oil of turpentine. The test 2 cc. of normal hydrochloric acid is added to the mixture shaken in order to make the reaction. This small amount of acid does not alter the reaction. The mixture is diluted 1 : 10 and 1 : 100. The first three rows of test-tubes (9 in each row) are numbered 0.9, 0.8, etc., to 0.1 (pure gastric juice), 0.9, 0.8, etc., to 0.1 (dilution 1 : 10), 0.9, 0.8, etc., to 0.1 (dilution 1 : 100).

The test-tubes are then filled with the milk and into each test-tube is poured 10 cc. of the milk. After the tubes have stood for one hour in a thermostat at 40°. In this way the coagulation is observed at a low temperature. The secondary coagulation with salts of calcium, whereby a secondary coagulation takes place at once on warming the solution. The undiluted solutions will be found coagulated in a few minutes. With normal gastric contents, with the addition of calcium salts, the boundary will be found in the

contents, the highest concentration of gastric juice will sometimes be found ineffective. In most cases, where with ordinary methods no coagulation is obtained, one still finds the test positive in the higher concentrations. If one does not wish to go to the trouble of preparing three sets of test-tubes, one may make a preliminary test with 0.1 and 0.01 cc. of the undiluted juice. This will show whether one should use a 1 : 10 dilution or 1 : 100.

As in the method of Blum and Fuld, one may express the results by the relation between the amount of gastric juice and the amount of milk used in the tube containing the smallest amount of the former sufficient for coagulation.

Estimation of the Fat-splitting Action of the Stomach-contents According to Volhard.—The fat-splitting action of the stomach-contents, which at one time, following the investigations of Marcet, Cash, Ogata, and Scheuerlen was thought to be due to bacterial action has been reinvestigated by Volhard. It has now been proved beyond question to be due to a lipase or steapsin.¹ This action is not inconsiderable, and has physiologic value. It follows the Schütz-Huppert law with regard to time and concentration, in which the degree of activity is proportional to the square root of the time of reaction and the amount of ferment. Volhard and Stade² have worked out a simple quantitative method for the estimation of the fat-splitting activity. The method which has been given by Riegel³ is as follows:

The yolk of one egg is diluted with 30 to 40 cc. of water, and to 10 cc. of this mixture a measured amount of the gastric juice is added after both have been previously heated to body temperature. The mixture is allowed to stand a certain time at this temperature. It is then cooled, placed in a separating funnel, and shaken out with 75 cc. of ether containing a few cubic centimeters of alcohol. A measured portion of the ether is transferred to a beaker, and 50 cc. of neutral alcohol are added. Phenolphthalein is then added, and the mixture titrated with decinormal alkali to a faint pink. To this mixture is then added 10 cc. of normal sodium hydroxid, and heated with a reflux condenser on the water-bath for two hours, using a soda-lime tube to protect the mixture from the carbon dioxide of the air. The flask may also be allowed to remain at room temperature for twenty-four hours. In this way one completes the saponification of the neutral fat. Ten cc. of normal acid are then added, whereby the fatty acids are set free. A second titration with decinormal alkali will give the amount of fatty acids which has not been formed by ferment action. From this, one may estimate the percentage of fat which has been split by the lipase in the gastric juice. The square of this number divided by the time of digestion gives the number of units of ferment contained in the gastric juice.

In cases of hypochylia and achylia, the amount of fat-splitting action is decreased up to total absence.

The butyrometric method may also be employed for determining the degree of fat-splitting. (See p. 487.) This is given from the difference between the acidity of the filtered and unfiltered contents of the stomach, after subtracting the acidity of the soup itself. In order to do this, the contents of the stomach must be boiled immediately after siphonage, in order to stop the further action of the ferment outside the body.

Examination of the Mucous Secretion of the Stomach

The gastric juice always contains mucus (mucin), in the form of more or less tough, transparent or cloudy flakes. If conditions be normal, these mucous flakes are always very small. They are easily stirred up in the rinse water. Swallowed mucus from the pharynx, esophagus, or bronchi is generally distinctive. It usually occurs in larger isolated lumps, and contains more pus-corpuscles than the mucus from the stomach. If it be foamy or pigmented (lung pigment), and if it contains no food-particles, which are so often intimately mixed with stomach mucus, the distinction is usually easy. The microscope will often solve the origin of the mucous constituents, for frequently in the interior of the mucous flakes a characteristic type of epithelium may be found, *e. g.*, pigmented lung epithelium. True stomach mucus, if the digestion be good, contains only the nuclei of large round or oblong epithelium cells and of leukocytes, because the cell plasma has been destroyed by the digestion. If the digestion be impaired, we can often see the cells of the stomach epithelium *in toto*. An increase in the amount of mucus, with an abundance of the polymorphous nuclei of leukocytes, is characteristic of gastric catarrh. We must be very cautious before assuming the presence of an increased

¹Zeit. f. klin. Med., vol. lii and liii.

²Stade, Inaug. Diss., Giessen, and Hofmeister's Beiträge, 1903, 3.

³Erkrankungen des Magens in Nothnagel's spec. Pathologie, 1908, second ed.

mucous production, for an abundance quite as frequently depends upon absence of a diminished production. Mucus swells considerably if free hydrochloric acid may seem increased. For this reason with carcinoma of the stomach, estimation of mucus, which is so difficult by chemical means. The mucus cannot be estimated fast, because the mucin which is dissolved by acid, or that which is even partly dissolved by acid.¹

The view that mucus is not digested is a common error.

Salomon's Test for the Contents of the Stomach Diagnosis of Cancer

Salomon has shown that in carcinoma of the stomach due to a new-growth, consisting of the exudate from the ulcer; and that the fasting stomach may be used as a basis for diagnosis. The stomach is thoroughly cleaned out by lavage and in the morning 400 cc. of physick's solution is given and by repeatedly raising and lowering the patient with the solution. Salomon estimates the nitrogen by Esbach's method, or the nitrogen content by the nitrogen determination. Salomon has shown that a well-marked flocculent precipitate is formed in 100 cc. of the solution.

Reicher² has shown that in carcinoma of the stomach the nitrogen content of the nuclealbumin. He believes that the nitrogen content of the surface of the ulcer. Reicher has shown that in the investigation of carcinoma of the stomach the nitrogen content did not exceed 1 per thousand, but in carcinoma the value exceeded 1 per thousand, even in those cases where both in the fasting and after food may be detected without difficulty.

Examination of Gastric Contents

Although it would seem valuable to study the changes in the digestive functions of the stomach, the chemical changes that the various foods undergo in the stomach, experience has proved this is not practical, for the changes from food to chyme depend not only upon chemical reaction but also upon the power of absorption and of excretion. The meal is rich in albumoses, for which digestion is especially good, but the albumoses formed are normally excreted in the intestine. An abundance of albumin in the amount of peptone contained in the chyme, generally speaking, distinguishes the normal from the pathological. Deductions could be based on the nitrogen content of the proteins of the chyme, but no available clinical methods for

⁴ This subject is treated in Neun

Bacteriologic Examination of the Stomach-contents

With added experience the author has come to the view that a large group of gastric disturbances is due to bacterial infection, a view which has been at variance with the conceptions regarding the antiseptic power of the gastric juice. How insufficient this antiseptic power is to prevent a profuse growth of bacteria is seen in cases of gastric stasis, in which condition no doubt exists as to the part which the micro-organisms play.

In cases of disturbance of the motility of the organ where the growth has been overlooked through exclusive attention to the test-breakfast, bacteria are a very important factor. This is due to the fact that examination of the stomach after the usual meal shows interference with motility, and partly that while the antiseptic power of the gastric juice is not entirely lost, the epithelium of the stomach-wall, when once damaged, takes part in the process only to a very small degree.

While the author previously recommended the bacteriologic investigation of the contents of the stomach after the flour-soup test-meal, he is now inclined to lay greater stress on the washings of the fasting stomach. One finds in this fluid the bacteria which have been swallowed with the saliva, but the appearance of large numbers of these, and the predominance of certain forms, especially after culture, has a very distinct diagnostic importance. Regarding the pathogenic quality of the micro-organisms, we are insufficiently orientated, but it is hoped that a careful study in this direction will yield results of very distinct value. Severe bacterial disturbances may be recognized from an examination of the vomit. (See p. 428.)

The Bacteriology of Gastric Carcinoma.—This is of especial value in the early diagnosis of cancer of the stomach. The frequent occurrence of the Boas-Oppler bacillus in the antacid or hypoacid contents of the stomach is characteristic. It is shown in Fig. 201 and is described on p. 430. This micro-organism has been called by Palier *Bacillus geniculatus*,¹ from the fact that two of the organisms bent at the end are found in close proximity to one another. The bacillus is non-motile, is 6 to 8 μ long, and is Gram positive. It often grows in chains. It is probably the most important lactic acid former in the carcinomatous stomach. It grows best in a limited supply of air. It is best grown in deep stab cultures in glucose-agar, at 38°. The bacillus may be isolated, according to Palier, by digesting 2 cc. of boiled meat and 5 to 6 cc. of the gastric juice. As the hydrochloric acid disappears from the gastric juice, the bacillus grows with the formation of lactic acid. Palier regards as especially characteristic of gastric carcinoma that besides the *Bacillus geniculatus*, there are found streptococci and staphylococci, few yeast-cells, and no molds.

The *Bacillus geniculatus* is also found in decreased acidity of the stomach without the presence of a malignant growth, so that one cannot assign to it, as was previously supposed, a distinct pathognomonic importance. It is, however, most suspicious when the organism persists in spite of frequent gastric lavage, and when the stomach does not present the signs of insufficient motility. In these cases there must be pockets in the stomach in which the organism lodges, and these are seen in organs affected with a malignant growth. It must, however, be pointed out that mistakes may be made even here. The author diagnosed a case as gastric carcinoma from the finding of the organism, and a metastatic recurrence of the same in the mucosa. The section showed that a metastasis had formed, but not in the mucosa. This was perfectly intact. A pocket was present in the stomach, due to operation in consequence of a gastro-enterostomy. In the pyloric end of the stomach was a pocket in which the bacilli were found in large numbers.

Examination of the Stomach-contents for Gas Fermentation

The fermentative processes which take place in the stomach when the digestion is affected, especially if there be also a motor insufficiency, have been studied recently, partly by bacteriologic examination and partly by chemical analysis of the gases which develop in the fermenting gastric contents, i. e., in the expressed test-breakfast. These examinations as yet have been productive of no practical results. The existence of fermentation can be demonstrated by placing some of the gastric contents in a fermentation tube (like the one used for estimating sugar in the urine) and letting it stand in an incubator (Fig. 238). If gas forms, it will accumulate above the fluid. If we wish to examine it more closely, we can collect the gas formed from a considerable amount of the stomach-contents in a larger vessel by conducting it through a tube and a pneumatic trough into an inverted tube filled with mercury.

¹Sandberg, Zeit. f. klin. Med., vol. li, p. 80, and Palier, Presse Médicale, 1906.

The gases which are found most frequently are hydrogen and marsh-gas, CH_4 . The former is easily absorbed by baryta water, and the marsh-gas, by the

DIAGNOSTIC IMPORTANCE OF THE

Concerning the value of Riegel's test-meal since from a motor as well as a chemical point of view it demands upon the stomach more than the ordinary food it acts as a greater stimulus to digestion. To better advantage existent anorexia appears perfectly normal, as indicated by the test-meal. Tested with Riegel's meal, show itself by not having completely emptied the stomach. Use of this test-meal there are of course various results to those given by means of the ordinary food. A chemical insufficiency of the stomach may be made to appear more plainly by the breakfast; on the other hand, anorexia that has escaped notice in the test-meal may be brought out by the strong stimulation of secretion. From these facts it is evident that in stomachic test-breakfast does not lead to a chemical test. It is to be repeated by means of Riegel's test-meal.

Concerning the most advantage of the Riegel meal, see p. 444. There are various results for us to be able to calculate the enzyme contents of the stomach-content. The fluid removed by siphonage, at various intervals of time, rule, it will be found that after four hours the Riegel test-meal will correspond to the ordinary fast after one hour, and that after six hours the stomach have easily emptied itself of the Riegel meal.

REVIEWS

The author, in the first edition of this book, encountered in using the Ewald test-meal the difficulty of being possible to say from the amount of fluid left in the stomach due to the meal, and how much is the residue. He has suggested that the fluid be left out of the test-meal. A single roll be given. One can in this way determine the quantity and character of the secretion. Boas¹ has shown that five Albert biscuits be given instead of a roll. The roll which should be avoided. This is not altogether true. The texture in ordinary bread have shown that the amount of food is not the important part. On the other hand, the use of the test-meal they cannot be swallowed without some quantity of saliva will be secreted, which is not the case with Bread which has not been baked too long.

BOUILLON

Talma² recommends a test-meal consisting of Liebig's extract, 0.3 per cent., which has been poured into the stomach with a stomach-tube. The investigations of Schiff and Herzen and of others show that the extract is exceptionally potent in promoting secretion. In form the method does not appear to the author to be

¹ Deut. med. Woch., 1907, No. 4.

eralization and the administration by a tube are both unphysiologic. Its advantage is that one is able to remove the contents of the stomach completely¹ has proposed to make the acidity of the gastric test-meal up to 10% HCl, and after a time to remove the contents, and to estimate the acidity of the contents. As water is not absorbed from the stomach, one can obtain information regarding an increase or decrease in the acidity. Naturally, such information, as a small amount of gastric juice of high acidity will give the same result as a larger amount with a smaller content in acid. Moreover, the addition of hydrochloric acid to the test-meal is another unphysiologic procedure.

CRITICISM OF THE FUNCTIONS OF THE STOMACH BY MEANS OF THE BUTYROMETRIC METHOD OF SAHLI AND SELER

It is hardly escape the thoughtful reader how great must be the tendency to attach to conclusions as to the functions of the stomach drawn from examinations of test-meals, even those in which the most exact chemical methods are employed. The main difficulty is the fact that the results of the quantitative examination of the contents are influenced by many different factors which do not admit of a separate calculation. For example, the amount of the test-meal is not entirely dependent upon the motility of the stomach, but is determined also by the quantity of the secretion. Again, the acidity percentage content does not represent directly the amount of the acid, but is influenced to a great degree by the motor activity. The acidity which is present indicates a very different secretory activity according to whether the expressed meal contains besides the gastric juice a greater or less part of the ingested test-meal, or according to whether a greater or less part of the secretion has passed, or is expressed, through the pylorus. If the greater part of the test-meal has passed quickly into the intestine during the hour before the examination, then even a small secretion may apparently be normal or subnormal; and the reverse is also conceivable—namely, that a normal secretion may present subnormal acidity, and perhaps even create a lack of free hydrochloric acid, in case the food which was ingested has passed only in small amounts into the intestine during the course of the observation. For the percentage content of free hydrochloric acid is influenced not only by the motility of the stomach, but also by the solution and absorption of the protein in that organ. It is quite plain, clear that if the proteins be quickly absorbed, the excess of acid will appear much more quickly than if at the time of the examination all the proteins of the food have been saturated by the acid. It must be emphasized that, if we determine the presence of a disturbance or abnormality in the gastric contents according to the older methods, it is not possible to say whether the disturbance is dependent upon the secretion or upon the motility or upon absorption, or upon all three factors together. If, then, we consider this, it must be admitted that the experiments of Pawlow, who succeeded in collecting gastric juice free from the admixture of water and food, were the only ones to give us exact data concerning the laws of the secretion by the

the preceding description of the usual methods of examination. In spite of the fact that even with the difficulties surrounding them, results have been obtained which are of value from a therapeutic point of view, it is evident the apparent accuracy of the results of these

¹ Review in *Semaine médicale*, 1908, No. 21.

methods as applied to the stomach is of the trouble which has been expended as actually lost, since it has not been results the separate factors mentioned in an equation containing several unknowns so long as other equations are not at similar lines, Pfaundler, in his very interesting several equations for the chemical examination found a method of getting more exact information and motility of the stomach. This consists in removing, during the periodic portions of the stomach-contents at a day or with a repetition of the test-meal, data obtained from the examination of the food used by Pfaundler to prepare equations to calculate, in absolute figures, the motor secretion of the stomach. But this method for practical purposes, and for the purpose of the present besides this, it is not entirely free from

Principle of the method

In order to obviate, in part at least, the inaccuracy of the examination of the stomach, the author resolved to add to the test-meal a substance which yet allows of ready quantitative determination and subsequent expression, from the results of the siphonage it can be calculated how much has entered into the intestine, how much is still retained in the stomach, and consequently what fraction of the expressed secretion of gastric juice. One obtains information of the motor activity of the stomach, and for the success of such a method it is necessary that the indicator must be homogeneous throughout, a substance which is an indicator of the motility the unabsorbed food is thoroughly mixed in the stomach-content, and does not separate or sediment; and, second, that the food should take place from the stomach. According to Mering, this latter fact may be considered concerning the choice of indicators for the examination the author thought first to add an insoluble substance to the test-meal, and to determine the amount of the food means or by counting the lycopodium spores, but he found, however, that neither the insoluble color nor the lycopodium was sufficiently well mixed throughout the stomach, so sure for the amount of the test-meal that the experiment was a failure. The author then tried powders attached themselves so intimately to the test-meal that the experiment was a success. Still another point to be considered is that the test-meal must not give it the character of a solid if this character consist merely in a taste. On this account the writer was led to the use of the food which appeared feasible for the purpose.

The use of fat in test-meals essentially for the sole purpose of the determination of motility had previously been proposed by Matthieu.¹ He added to a test-meal consisting of 60 gm. of bread, 20 to 70 gm. of oil, in the form of an emulsion with gum, and 250 gm. of tea. He then obtained by means of the determination of fat data concerning the motility and secretion of the stomach, although the latter was merely incidental and was not carried out to any definite conclusion. The author does not know whether this method of Matthieu has been found to be practicable. In any case this test-meal did not appear to the author to be available for the point in question, because it did not fulfil the postulate of homogeneity, in that the pieces of bread exhibit a decided inclination to sediment, and thereby mechanically remove an unknown part of the fat. In consequence of this the fat, other food constituents, and the secreted juice do not allow of quantitative determination. Besides this, such a mixture of an emulsion of oil with the ordinary test-meal cannot be considered as a usual diet, nor on account of its unpleasant taste is it a test-meal of physiologic composition. The experiments of Pawlow show sufficiently how very easily the physical characteristics of the test-meal influence the functions of the stomach.

Again, v. Mering, in his method of proving the power of absorption of the stomach, employed fat in the form of an emulsion of the yolk of egg. T. Volhard, nevertheless, has shown that such emulsions of the yolk of egg are not permanent within the stomach; as a result of the influence of the hydrochloric acid, the egg-yolk separates, and the postulate of homogeneity is consequently not fulfilled.

The attempt was made next to use milk, since this presents a mixture of protein, carbohydrate, and finely divided fat, which is easily obtainable and nearly ideally constituted for the purposes of nutrition. The experiments with milk resulted unfavorably, in that the coagulation of this substance which took place in the stomach disarranged its homogeneous composition. It was easy to show that in the coagulation the fat was carried down almost completely by the precipitation, and that the coagulum and whey in the expressed test-meal of milk contained very different amounts of acid. We were not able by various artificial means to compel the milk to coagulate in fine flocks, and thus to avoid any considerable appearances of sedimentation in the stomach. The employment of milk was consequently also excluded.² Finally a soup made of flour browned in fat proved to be adequate for our purpose, and yet completely suitable for ordinary nutrition. At the author's suggestion, his assistant, Dr. Seiler, tested the feasibility of the employment of this test-meal for the purpose in hand, and made a number of examinations, which have been published in his dissertation.

Preliminaries of the Method

Preparation of the Flour Soup.—This can be very readily prepared by the physician immediately before the examination, and requires only a few minutes' time. The method is as follows: 25 gm. of flour and 15 gm. of butter are fried in an iron pan until well browned³; and about 350 cc. of water are then added gradually with constant stirring. The mixture is then boiled for five minutes, and the loss in volume replaced by fresh water. Salt (sodium chlorid) is now added to give the soup a pleasant flavor. The mixture must not contain any lumps. This soup presents a well-mixed emulsion of fat, which, probably because it is mechanically well mixed with the flour, remains

¹Arch. f. Verdauungskrankh., 1896, vol. i.

²A further reason for abstaining from the use of milk was the fact that, in opposition to the results of Schüle (Zeit. f. klin. Med., vol. xxviii), the author was never able to detect free hydrochloric acid in an expressed test-meal of milk of 200 to 300 cc. This difference is attributable to the better quality (fat and protein content) of the cows' milk used in his laboratory.

³The flour may be fried beforehand and kept in tins in a cool place to prevent the melting of the fat. As the flour is sterilized by the process, the mixture keeps for a long time. In this way the procedure is simplified, as one has only to weigh out 35 gm. of the flour, and boil it with water in order to form the soup. In many instances the objection which has been raised to the method is based on the improper preparation of the soup. When once the method has found general application, which is only a matter of time, the flour will be prepared on a commercial scale, and be available at any time.

intact, in spite of the action of inclination within the time of the fat to separate.¹ In fact, soup is expressed in about the duced. It is merely more or less

may have been split in the stomach, it cannot serve as an indicator for the acid. The separated glycerin and butyric acid are both soluble in water, and, if they consequently remain in the watery, it and thus escape estimation. The action was studied by the author's assistant, published in the Archiv für klinische Medizin; the amount of fat decomposed is so small that it can be neglected. The flour soup is especially well adapted. It has been shown that the lipolysis in this soup is very rapid. Furthermore, almost all of the fatty acids are insoluble in water, so that they pass into the alcoholic layer of the butyrometer. The water in water, is present in such exceedingly small amount that it is disregarded. Owing to the relatively small amount retained in the fat, it follows that even the loss in the alcoholic layer due to water is so slight that it is practically negligible. The fatty acids liberated by lipolysis in the fat, and the result will be fairly accurate.

Although lipolysis does not interfere with the titration, Volhard has shown that if the juice be small in amount, the acidity of the acids by lipolysis may markedly influence the result, consequently be incorrect to refer this acidity to chloric acid. The simplest method for the determination of the filtered gastric contents for the titration is the exception of the quantitatively unimportant insoluble acids, which are insoluble in water, and so, since the acidity of the filtrate may be referred

The process is as follows: 5 cc. of 1.820 to 1.825 at 15° C.) (corresponding to 1.820 to 1.825 at 15° C.) is added to the small butyrometer by means of a graduated glass tube. The liquid is stratified 0.5 cc. of pure amyl alcohol and then 5.5 cc. of the flour soup or water. The butyrometer is then carefully closed by means of a stopper and is thoroughly shaken. On account of the heat of the liquid, the stopper is covered with a cloth. It is finally centrifugalized, during which the fat and alcohol separate. The end of the butyrometer must lie toward the center of the centrifuge. After centrifugalization the fat and alcohol separate into a clear, transparent layer on top of the colored layer. Centrifugalization is carried out in a centrifuge.

alcoholic layer increases. In case the operation is not undertaken immediately, the butyrometer must be placed in water at a temperature of at least 70° C., in order to prevent the hardening of the fat. In order to obtain exact results the reading should be made while the fluid is still warm. For the purpose of reading, the rubber stopper must be pushed into the mouth of the butyrometer so that the upper surface of the layer of fat (with its under meniscus) comes to lie at the zero-point of the scale.¹ The scale (empirically graduated) is then read off at the point corresponding to the lower meniscus of the fat-layer. The centrifugalization should be repeated, particularly by those who are inexperienced in the method, in order to insure the accuracy of the estimation. If the estimation be correct, the second centrifugalization must give exactly the same reading as the first. Gerber found that this method for the determination of fat is exact for milk to about 0.1 per cent. Control experiments which were undertaken at the author's suggestion, in order to compare the results from this instrument with those from the Soxhlet apparatus, have shown that this degree of accuracy holds good for the flour soup before and after the action of stomach digestion.

Method of Fat Estimation Without the Use of a Centrifuge.—The open butyrometer is filled (Fig. 209, b) by closing the smaller end with a cork, and placing it in a test-tube rack with the larger end upward. After the flour soup has been warmed and thoroughly mixed by shaking, 10 cc. of the soup are poured in, and 1 cc. of amyl alcohol and 10 cc. of sulphuric acid added by allowing them to flow down the side of the tube in order to form a layer. The larger end is now closed with the rubber stopper. As the contents of the tube become warm it is necessary to hold both stoppers firmly with the hand. It is, however, wise to inclose the tube in a towel, in case it should break with the heat evolved. This rarely happens. The tube is then shaken, both stoppers being firmly held by the fingers. As soon as the mixture is complete, the upper, smaller stopper is removed. The tube is then placed in a boiling water-bath, adjusting the lower stopper so that the fluid is not high in the neck. From time to time the stopper is so adjusted that the layer of fat which is formed is just under the neck. The butyrometer is not placed directly on the bottom of the water-bath, as the formation of bubbles disturbs the tube and prevents the formation of fat as a homogeneous layer. Several tubes may be charged at the same time. After the butyrometer has remained for ten minutes at boiling temperature, the foam which is at first formed disappears, and the first reading may be made. In order to do this, the butyrometer is taken out of the water-bath and, being held in a slanting position, the lower stopper is so adjusted that the layer of fat rises within the limits of the scale. This must be done carefully else small particles of other substances than fat will be included in the layer. As soon as the fat is in the proper position, the tube is held vertically and the amount of fat read off. Each division corresponds to 0.1 per cent. fat. It is not necessary to adjust the fat layer to zero: it is only requisite to read the difference between the upper and lower divisions. With practice one obtains a perfectly sharp separation of the fat from the aqueous layer. In cooling, the layer of fat contracts, so that the reading must be made as rapidly as possible. The separation is not so well marked as by the use of the centrifuge, but the clear layer is sufficiently well defined. As a consequence of the longer heating of the flour soup with the acid there is much more carbonization. This does not, however, interfere in the least with the reading. If the separation be not perfect, the attempt may be made again by gently reversing the tube, and also by placing it again in the water-bath. In any event it is advisable to reverse the tube, in order to obtain a control of the reading. The larger value is always the correct one. One

¹ In centrifugalizing it will be found more practical to introduce the rubber cork so that the upper level of the fluid reaches only to about the 80 mark of the butyrometer scale, since the fat accumulates most readily in the conic part between the neck and the body of the butyrometer. By observing this precaution, moreover, the disturbing layer of insoluble substances (cellulose, etc.) collecting below the fat may be kept back in the wide portion of the butyrometer by cautiously bringing the instrument into the vertical position when the rubber cork is pushed in.

Performance of the Method

After a thorough rinsing of the stomach the patient is given in the morning 300 gm. of flour soup, prepared according to the method described.¹ The remaining 50 cc. are retained for the determination of fat. After one hour the contents are expressed, as described above. A rest estimation, as was previously recommended, is unnecessary, as nothing remains in the stomach. The organ is washed out with 300 cc. of water. If the siphonage has been carried out, the washings should contain but traces of the flour. Next, the amount of fat in the undiluted stomach-contents, and in that portion of the soup which was retained as a control, is determined butyrometrically according to the method given above. The undiluted stomach-contents still remaining can be used for whatever qualitative or quantitative determinations may be deemed advisable. These examinations in this case normally show the same results as those of the ordinary test-meal. Free hydrochloric acid should be present, lactic acid should not. The flour-soup meal is very well suited for the determination of the pathologic formation of lactic acid, because it is free from this substance. In order to eliminate the fatty acids, titrations are carried out with the filtered gastric contents. If these are also carried out with the unfiltered soup to which a quantity of alkali has been added, the difference in the two titrations will give the amount of fat-splitting which has been performed by the gastric contents. In order to obtain comparable results, the same amount of alkali must be added to both. A correction must also be made for the alkali of the flour soup itself. This, according to Seiler, is equal to 0.2 to 0.3 decinormal alkali. Seiler has shown that the soup contains a small amount of free fatty acids. The titration must be carried out immediately after the siphonage, as the fat-splitting may precede after the contents of the stomach have been removed. This may be avoided by titrating the contents immediately after removal. (See Seiler, *Deut. Arch. Klin. Med.*, lxxii). Besides the total acidity, the excess or deficit of free acid may also be titrated. If the qualitative reaction shows considerable amounts of lactic acid, the determination of the hydrochloric acid may be made by Lütke-Martius' method, or that of the hydrochloric acid and the organic acids by Hehner-Maly's. Of course, all other examinations can also be made upon the expressed gastric contents—namely, the qualitative and quantitative tests for pepsin (pp. 465 and 473) and the ordinary tests for starch digestion.

The author recommended originally that the soup be eaten with a spoon. As it is not at a considerable quantity of saliva is swallowed in this way, it may be better to allow the patient to drink the flour soup. This may be an advantage over the ordinary test-meals. The author is not altogether in agreement with this view, as the saliva is a necessary ingredient of the gastric contents. If it be assumed that the amount and acidity of the gastric contents in the butyrometric test are influenced by the saliva, in a case where the gastric contents are copious and the amount of acid small, a second test may be made by allowing the patient to drink the soup.

Calculati

The following calculations are based on the residue, from the acidity of the stomach-contents, between the amount of the fat found in the expressed contents.

We measure the amount of fat absorbed (if it has been complete, we designate it as T_1 (one hour)). From the absolute fat-contents there can be determined how much fat is left to the ingested flour soup, provided it is thoroughly mixed emulsion without disturbance. Since the results of the fat-contents of absorption of water from the stomach-contents of fat in the stomach may also be determined by the fat to the stomach-content of the stomach nor by the absorption of gastric juice. The amount of fat absorbed is therefore, as a measure for the fat-contents, for example, if 300 cc. of flour soup, or altogether 12 gm. of fat, were determined for T_1 to show the amount of fat absorbed, the amount of fat absorbed the period was equal to $T_1 \times 300$ this amount as Su (soup).

Since we can neglect the absorption of saliva which was swallowed, the volume of gastric juice present in the stomach, designate as Ma (gastric juice). If $Ma = 75$ cc., and the amount $Su = 75$ cc. of gastric juice contained in the stomach has been determined, it is possible to calculate what acidity was present in the stomach was secreted from the mucous lining.

If 75 cc. of pure gastric juice were added to the stomach whose volume amounts to 150 cc. of gastric juice, the acid content of the pure gastric juice would be a thousand. In a similar way the acidity of the stomach-contents can be calculated if it has been determined.

In order to avoid misunderstandings in these calculations, attention must be paid to the following.

Naturally, the volume Ma is

¹ The fat-splitting of the soup which was determined (p. 484.) The amount of water-soluble fat which can be absorbed from the stomach-contents.

² In this conception of secretion the stomach-contents may be excited by the flour-soup test which contains water-soluble carbohydrates and salts. This place only in stomachs with disturbed secretion. Into account here, and where the estimation of a very large amount of gastric juice, one part of the contents with saliva. In such cases the patient drinking the soup. In this way (p. 487.)

ed up to the time of expression. Juice mixed with the food has been expression. Nevertheless, the calculation of the volume of the secretion independent of the pure gastric juice, since it is of the gastric juice present in the amount of test-meal present in the various examples will show, this relation is normal conditions. The gastric juice volume T_0 is approximately equal; variations in this relation are of

the motility of the stomach which the following is to be noted: The juice introduced and that recovered ($300 - S_u$) can be considered as a value. Really this value does not correspond to the stomach, for an unknown amount has also been passed on into the duodenum. Probably a more reliable measure of the total stomach-contents, which serves the same purpose. For, as already stated, the juice contains under normal conditions gastric juice, so that it is easy to determine normal occur, whether a hypersecretion. This gives the actual value

Advantages of the Flour-soup Method for the Stomach

The author has shown, in a recent (1905, No. 27 and 28), that the flour-soup bacteriologic examination of the stomach preparations of the siphonage are made. He shows the usefulness of the method in conditions belonging to catarrhs and those associated with hypochlorhydria. Bacterial growth is seen. As the soup in the stomach is the advantage over the ordinary test-media, it is assumed that the flora of the stomach will be more complete, and the Boas-Opler bacilli of carcinoma. Other groups of micro-organisms, although they are not well characterized, are also present. These may, by their chemical and physical properties, be of all degrees, and may be of great importance, but cannot be detected by the ordinary test-media. The author recommends further examinations of the bacteria of the stomach.

The Objections to this

Almost immediately upon the publication accuracy was attacked by various authors who chief objection made was that the mixture of the arated into layers within the stomach, so that a and other contents did not occur, and that con contents could not be taken as an indicator for This objection was based upon the observation in two portions, one corresponding to the upper, there will frequently be a difference in the amount This observation was founded upon fact. A co contents is not usually present after the introducti suggestion this question has been carefully studi lished their results in a recent article.¹

It was shown in these experiments that when removed in two portions and the fat-content of the between the two was represented in 33 cases by

0, $\frac{1}{8}$, $\frac{1}{4}$, $\frac{1}{2}$, $\frac{3}{4}$, 1, $\frac{1}{8}$, $\frac{1}{4}$, $\frac{1}{2}$, $\frac{3}{4}$, 1, $\frac{1}{8}$, $\frac{1}{4}$, $\frac{1}{2}$, $\frac{3}{4}$, 1, $\frac{1}{8}$, $\frac{1}{4}$, $\frac{1}{2}$.

These investigators used the most unfavorable upper layers were siphoned off, and only small portions removed. Saliva or gastric mucus would, therefore, be expected to give such results. In spite of this the variations were extremely small. That for clinical purposes the results are on a par with those obtained in the other cases will be seen that in most of the cases this difference was the difference greater. The maximum difference was $\frac{1}{2}$. This may have been due to the admixture of saliva. In both cases the upper layer contained the less fermentable material. It should be mentioned that there was much hypersecretion.

If we designate the relation of the two layers fluence which the two layers have. Practically, the whole contents are removed at the one time of those who have criticized the method it is necessary of the question. Taking the difference of the layers calculate these values for f (fat-content) and $\frac{n}{m} \cdot f$.

¹ Deut. Arch. f. klin. Med.

$$Su_1 = \frac{L \cdot To}{F} \text{ and } Su_2 = \frac{\frac{n}{m} To}{F} \therefore Su_2 = \frac{n}{m} Su_1.$$

$$\text{also } Ma_1 = To - Su_1 \text{ and } Ma_2 = To - \frac{n}{m} Su_1.$$

$$A_1 = \frac{aTo}{To - Su_1}, \quad A_2 = \frac{aTo}{To - \frac{n}{m} Su_1}.$$

sees that the most important value Su in the maximum error due to stratification is $\frac{1}{3}$ of the fat content. If only a part of the contents of the stomach be re-estimated the values may vary between 2 and 3. Even as great a variation as this is of great importance in practice. The errors in the values Ma and A , as the foregoing shows, are influenced by the errors in the size of To and the error in the estimation of Su . The smaller they are the larger is To .

In the calculation of the maximum error, where the relations stand as 2 : 3, placed the method in an unusually unfavorable light, but as this variation occurs seldom, and the total contents of the stomach are removed at one time, it appears that this may be assumed to be almost infinitely small. It seems that in this regard the critics of the method have totally misconstrued it. It might have appeared that the now discarded method of estimating the rest of the stomach-contents that the author suggested partial siphonage, but this was not the case. All the investigations of the stomach-contents which were carried out in the author's clinic were with the total contents of the stomach. This was very clearly pointed out in the work of Seiler and Ziegler, who removed the contents in the knee-chest position, drawing the stomach-tube gradually. This may be done more easily with a tube having more than one opening. The rest estimation simply takes into account the small deficit in the siphonage. For the total calculation it is of minor importance. The author wishes to point out again the importance of the procedure which is recommended for completely emptying the stomach.

It may be objected that although in the perfect siphonage of the stomach the error due to time of removal is eliminated, yet one does not exclude the fact that during digestion the fat and the other materials in the stomach are not perfectly mixed and thus the whole examination is rendered illusory, it can be shown that this criticism does not hold. The method only gives the conditions in the stomach at the time of the siphonage. The experiments of Seiler and Ziegler showed that the portions which were richer in fat were not always the upper ones. Hence the question of stratification can only be concerned with the idea that particles containing much fat rise to the top, while the rest of the flour falls to the bottom of the stomach, and at the same time carry fat with it. As a consequence of the irregularity of the mixture both are probably excluded. The differences are probably due to the incomplete secretion of the gastric juice at certain places, and its incomplete mixture with the flour soup. The final mixture of the contents of the stomach before the estimation of fat brings all these differences to a practical zero. The lack of homogeneity of the contents is due to regional differences in the secretion of gastric juice. This was shown by Seiler and Ziegler. They made experiments in which the patient changed his position every five minutes. The position did not markedly affect the differences in the fat estimations. Seiler and Ziegler have shown what small movements of the stomach are sufficient to prevent sedimentation. They carried the contents of the stomach about for ten minutes. The movements of walking were quite sufficient to prevent stratification.

This would also be done by the slightest peristalsis of the stomach. In case of motor insufficiency of the stomach one might have stratification. In these cases one might not have a true picture of the gastric motility. In spite of this the soup method has the advantage over others in that at the end it differentiates between secretion and fat. Prym has tried to show, with experiments on dogs, that portions of soup colored with different dyes, that the portions recovered still retained their original color. This is a confirmation of the fact that stratification does not occur. Had such taken place, the whole of the contents of the stomach would have been uniform in color. The author does not believe that thorough mixing of the contents of the stomach occurs by peristalsis. Finally, Strauss and others have endeavored to replace the present method, using rusks with fat. This is to be a step backward, as the solid rusks sink in the stomach, and are

In this last edition the author suggests that a diagnosis of hyper- or acidity should not be made from the hydrochloric-acid content of the total stomach-contents, but that the amount which was present in the free gastric juice should be calculated. This suggestion has not been found to be practical, for, in the first place, it is against the common practice, and, therefore, leads to confusion, as up to this time the diagnosis of hypo- and hyperacidity have been made from the analysis of the total contents of the stomach. He now suggests that the anomalies in the diagnosis which are made out by means of the flour-soup test-meal should be designated by the words hyper- and hypoacid secretion. By the term hypoacid secretion is understood a deficiency in the acid content of the free gastric juice. By the terms hypo- and hypersecretion or hypoperachylia are understood the changes in the volume of gastric juice. As a basis for this estimate we should not take the absolute amount of gastric juice found in the stomach after an hour, but, better, the amount of gastric juice in proportion to that of the soup still present in the stomach. It is this relative amount which is of value for judging the secretory power of the stomach, because, while at every moment a certain amount of gastric juice and soup is being removed into the intestine, the relative amount of soup and gastric juice expressed is not indeed changed by the motility. Seiler is quite right to call this relation of the amount of secretion to that of the flour soup remaining in the stomach the "secretion quotient." This is normally not far from 1. Considerable values above 1 would argue for the diagnosis of hypersecretion; below 1 for the diagnosis of hyposecretion.

The motility of the stomach may then be said to be normal if, after ingestion of 300 cc. of flour soup, not more than 100 to 150 cc. is expressed at the close of one hour, of which about one-half consists of free soup. Therefore, the ratio of the amount of juice to that of soup recovered, as expressed by the secretion quotient, must be considered in the estimation of the motility. For example, if the amount of juice remaining be absolutely normal, but a relatively greater amount of soup is found, this amount of soup points not to a normal, but rather to hypermotility. So a normal amount of soup with diminished juice points to a decreased motility. The ratio of the amount of soup removed during one hour from the stomach into the intestine to the amount of soup ingested, $\frac{300 - Su}{300}$, may be called the motility quotient. This varies normally between three-quarters and nine-tenths, and must be interpreted, as has been said, by the consideration of the secretion quotient.

It is evident from the above that it is possible to discover by this method a number of conditions which must have completely escaped the older methods of investigation. By it it is possible to decide whether an increase in the amount of the expressed stomach-contents points to hypersecretion or to a motor disturbance. It is also possible to differentiate more exactly than before between hypersecretion and hypermotility, since the volume of secretion, as well as the acidity of the pure gastric juice can be differentiated. Experience with this method has shown us already that gastric disturbances are decidedly more common than had heretofore been imagined. The more exact differentiations it enables us to make will, in the future, increase our diagnostic possibilities. It has shown us, for example, that there are

cases of hypersecretion with hypo-acid with hyperacidity.

This condition is possibly due to an abnormal previously referred, and which we have trace soluble products of digestion. (See p. 488, for

These conditions, by the old methods because in such cases the amount of gastric juice in mixed gastric contents other in the determination of the total greater part those cases diagnosed usual in spite of disturbances of digestion, the contents by means of the usual methods results. That the present simple and of the symptomatology of the diseases or decreased secretion and excessive suffer decided alteration may be shown some functional diagnoses which we are of the new method:

A. CASES WITH SUFFICIENT MOTILITY

1. Hypersecretion with hyperacidity
2. Hypersecretion with hypo-acidity
3. Normal amount of secretion and motility.
4. Hyposecretion, hyperacidity
5. Hyposecretion, hypo-acidity and motility.

B. CASES WITH INSUFFICIENT MOTILITY

6. Diminished motility, hyperacidity
7. Diminished motility, nearly normal

More extended experience will certainly bring new combinations.

From the preceding recapitulation it is the attempt of certain authors to ascribe acidity and hypersecretion to primary meaning the cause to pyloric stenosis, a view enterostomy in cases where such an operation. These more exact functional diagnoses are important also in a therapeutic connection clearly whether it is best to influence expression of stomach-contents) or to use preparations, alkalis, by employment secretion directly by means of the appetite extract, bitters.—Ed.]).

Further Value of the Butyrometric Method of Estimating the Amount of Amylolytic, Absorption of Carbohydrates and of Proteins by the Stomach.

What has already been said concerning the method of the examination of the stomach-meal has not exhausted the possibilities of the method, to the quantitative testing of the digestion the following method is much more exact than the

confessed that it has not been as yet practically worked out. The ex-
 tomach-contents, as well as the undigested flour soup which was retained
 trol, are examined butyrometrically for their fat-content. Then equal
 of both of these fluids are measured off, each thrown upon a separate
 and washed with water so long as the filtrate still shows a starch or sugar

This is to remove the soluble products of the starch digestion. In
 ue on the filter in each case the starch content relatively to the content
 soluble carbohydrate is determined, and the difference in the two amounts
 d for the unit of the fat-content shows how much of the starch has been
 ned in the stomach into soluble carbohydrates, i. e., has been digested.

soup meal can again be employed for the determination of the power of
 n of the gastric mucosa for soluble carbohydrates. Equal amounts of
 esed and retained flour soup are hydrolyzed, and in each the sugar tested
 ively. The amount of fat in the two fluids must also be determined
 etrically. The content of sugar which is found in the expressed con-
 ves as a measure of the total soluble and insoluble carbohydrates which
 tained in the stomach and not absorbed. If we therefore subtract this
 calculated for the unit of fat-content, from the sugar of the undigested flour
 pressed in the same way, there will be obtained the amount of the absorbed
 rate in terms of the unit of fat-content.

order to understand this value correctly it must be emphasized that the
 rates which are introduced by this method into the stomach do not, for
 part, occur in a preformed absorbable form, so that the power of absorp-
 ound, appears at the same time as a function of the digestion of carbo-

If one wishes to determine the amount of the absorption by itself,
 v. Mering method of determination, it must be considered how much sol-
 carbohydrate is contained in the ingested flour soup and how much of car-
 e was transformed into a soluble condition during the digestion

interpretation of the relations of carbohydrate digestion and absorption
 shown in the following way:

C_1 = the carbohydrate of the undigested flour soup.

C_2 = the carbohydrate of the undigested flour soup minus the soluble car-

C_3 = the carbohydrate of the expressed flour soup.

C_4 = the carbohydrate of the expressed flour soup minus the soluble car-
 e. Then $C_2 - C_4$ = a measure of the carbohydrate that has been digested,
 ured soluble.

$C_1 - C_3$ = a measure of the absorbed carbohydrate.

$$\frac{C_1 - C_3}{(C_1 - C_3) + (C_2 - C_4)} = \frac{\text{carbohydrate absorbed}}{\text{carbohydrate originally soluble and that dissolved}} =$$

 bed fractions of the carbohydrate originally soluble and dissolved during
 tion.

latter fraction, in an analogous manner to the secretion and motility
 may be called the absorption quotient of the carbohydrate.

ly, the butyrometric determination can be used to test the digestion and
 n of proteins under natural conditions. Here also the method must be
 oughly worked out technically, but the plan of the examination appears
 arly outlined. The process is entirely analogous to that for testing the
 rate digestion. After the fat in the undigested flour soup, as well as in the
 stomach-contents, has been determined, each fluid is filtered, and washed
 soluble proteins with water. In all four tests the nitrogen content as deter-
 the Kjeldahl method serves as a measure of the total proteins, including
 and peptones. All of these values must be calculated for the unit of fat-

N_1 = the nitrogen content of the undigested flour soup.

N_2 = the nitrogen content of the undigested flour soup minus the nitrogen
 ible proteins.

N_3 = the nitrogen content of the expressed stomach-contents.

N_4 = the nitrogen content of the expressed stomach-contents minus the
 of soluble proteins.

N_5 = amount of soluble nitrogen in the undigested test-meal.

N_6 = amount of digested, i. e., soluble, nitrogen.

N_7 = amount of resorbed nitrogen.

$$\frac{N_1 - N_5}{(N_1 - N_5) + (N_2 - N_6)} = \frac{\text{absorbed } N}{N \text{ soluble and that dissolved}} =$$

the measure of that part of the solid made soluble by digestion, which was the *nitrogen quotient* of the proteins.

Concerning the Technic of the Carbohydrate in These Examinations.—The only if the carbohydrate be complete as such. For this purpose, according to contents or flour soup are treated with the positive Congo-red reaction, the sulphuric acid (5 cc. of dilute sulphuric acid with water), and the mixture heated under pressure flask in a paraffin bath, and is added to a small portion.

Pavy's method is used for the detection (p. 620.) Not only albumin, but protein many experiments the author has found as the albumoses and peptones, can be in mixture, thorough washing with water, and with a solution of phosphotungstic acid. The solution must not contain hydrochloric acid either for the hydrochloric acid solution.

After the precipitation of the protein from the filtrate.² This is best accomplished as an effervescence takes place. The filtrate is free from proteins, and can be examined by Soxhlet-Allihn, colorimetric or

Where it is simply a question of the expressed meal in comparison with the expressed meal, the colorimetric method of Ambuhl.³ But since the meal is in soluble condition, and since this meal, causes a dirty brownish-violet coloration, the determination of the starch must be made especially the erythro-dextrin, have been determined by repeatedly washing the expressed meal in a centrifuge. It must be mentioned that the soluble constituents by means of the expressed contents have been extracted by means of the separation of the undigested and of the expressed meal, of a pipet calibrated to hundredths of a centimetre with ether until a test of the substance remaining part is boiled for ten minutes. The greater part of the starch passes into solution and is added drop by drop to the solution more intense. The shades of color are compared, and it is determined in a measured amount, be diluted in order to correspond to the dilution necessary for this purpose in the ingested to that in the expressed

⁴ Cent. f. inn. Med., 1892 and 1893.

than by the stomach itself, since nutritive substances reaching the intestine effect a reflex closure of the pylorus (von Mering's reflex) until the intestine has completed its work. It consequently seems to the author to be inadmissible to regard the emptying of the stomach as a pure question of strength, as would be suggested by the term insufficiency or motor weakness of the stomach, since even a well-developed and efficient stomach does not empty itself if it be opposed by the intestine. Actual weakness of the stomach nevertheless does occur, and, in order to differentiate it from the more frequent forms of disturbed motility which proceed from the intestine, a special method of examination is necessary, which the author will now give, and which he has carefully tested in recent years. The motor activity of the stomach must be examined under conditions in which von Mering's reflex does not occur. As von Mering and Marbaix have shown, such a condition is present when the stomach contains water alone, since, under physiologic conditions without obstruction, the water is emptied into the intestine within a short time. We must consequently determine the length of time required by the stomach to empty itself of a definite quantity of water—a half liter, for example.

Since we have to do with stomachs which do not empty themselves well, the test must be preceded by a thorough cleansing of the organ. The stomach must be completely emptied of the rinsing water by the method described on p. 445. The patient then drinks the prescribed quantity of water, the gastric contents are then expressed in a half-hour, and the quantity passed onward into the intestine is thus determined. Here also the above-mentioned method is used to evacuate the stomach. The residue estimation, using methylene-blue, which was suggested in previous editions of this book, is quite unnecessary. The method has therefore gained in simplicity.

The test for "gross motility," must be carried out with the patient in the upright position, since gravity interferes too much with the expression if the patient be lying down.

Special Examination of the Stomach for Pyloric Stenosis

Pyloric stenosis is diagnosed much too frequently nowadays when the stomach fails to empty itself properly. In reality the case may be simply a functional disturbance of von Mering's reflex or a condition of motor weakness. It is, therefore, desirable to be able to detect stenosis directly. Moritz has shown that the stomach is an excellent sedimenting apparatus, and that in all forms of impaired motility firm, indigestible substances (fruit kernels and other vegetable constituents) may remain in it for days, since they are never elevated to the level of the pylorus on account of their high specific gravity. We are consequently not justified in diagnosing a pyloric stenosis offhand from the presence of such old substances in the retained gastric contents. A little reflection will also show that the retention of indigestible substances of a specific gravity low enough to enable them to float may be utilized to diagnose a pyloric stenosis the caliber of which is not sufficient to allow of their passage. This is the basis of the procedure the author recommends, by which it is possible to diagnose the existence and caliber of a pyloric stenosis by the administration of little balls of cork. The patient to be examined for pyloric stenosis is made to swallow a ball of cork 1 cm. in diameter. If the cork ball be found in the stool the following day, the pylorus must be large enough to have allowed it to pass. On account of its low specific gravity, the cork ball may easily be found, since it readily floats when water is added to the stool. If, however, the ball be not found in the stools after several days and the administration of a spoonful of castor oil, a stenosis of the pylorus of less than 1 cm. is indicated; for even in the most severe disturbances of gastric motility if the latter be not associated with stenosis the sphere, on account of its low specific gravity, does not sink to the low-lying portions of the stomach and remain there, but finds its way into the intestine. Certain precautions must be observed, however, in carrying out this test. After swallowing the cork the patient should lie in bed for a half-day, preferably upon the left side, so that the ball may be floated upward into the neighborhood of the pylorus. If the stomach is markedly loop-like, it may be sufficient to have the patient lie upon the left side for a short time, under the supposition that the cork ball is immediately floated toward the pylorus and remains there. The author has not yet employed cork balls larger than 1 cm. in diameter, for fear they might stick in the esophagus. To what extent the caliber of the ball may be increased remains a subject for further study.

Recently, the author has modified the method by using, instead of solid pieces of cork, sacs of rubber containing cork filings made like the desmoid sac, which are

tied with a piece of catgut the size of a 2 per cent. formal solution for two hours. the permanent remaining of a solid piece. This might float to the pylorus, and act as a plug. Catgut hardened in formaldehyd is very difficult to pass in the intestine. It is, however, finally dissolved. In order to ascertain whether the retention of the catgut or to occlusion, a metallic bismuth. This is included in the sac. It has been dissolved, from the appearance of the contents. Prepared with especial care in order to pass the neck. This can be avoided by wrapping the neck. This process has often been of great distinction between functional disturbance and pyloric stenosis.

DETECTION OF CERTAIN POISONS IN THE

ARSENIC

In most cases of acute arsenic poisoning may often be found as white, insoluble powder. If the arsenous acid has been used in solution, the suspected material with a piece of copper or gray layer of the amalgam of arsenic wrapped into a piece of hard glass tubing drawn out at one end, and both are heated gradually in a flame. The acid is reduced to metallic arsenic, and a bluish mirror is formed on the inner surface of the glass. The Marsh test is more delicate and is performed with a thistle tube and a flask. The outlet tube of the thistle tube is drawn out in the form of a hair, and a piece of hard glass drawn out in the same way, is placed in the flask, and hydrogen gas is passed over it. The hard glass tube is then heated for some time, and the arsenic is reduced to metallic arsenic in the reagents used. The mirror is formed on the inner surface of the thistle tube. If the substance contained arsenic, the flame formed by the hydrogen is colored with a bluish flame. If a porcelain plate is held over the mouth of the tube, a mirror of metallic arsenic is formed. A similar test is performed with antimony, distinguished by the fact that it is only when the tube itself is heated, an arsenic mirror is formed.

HYDROCYANIC ACID AND ITS SALTS

Hydrocyanic acid and potassium cyanide of the stomach are characterized by the following substances, the acidified mixture is distilled with sodium hydroxid. Ferrous sulphate solution made acid with hydrochloric acid, and a solution of hydrocyanic acid Prussian blue is formed. By adding to the distillate a few drops of ferric chloride, then evaporated to dryness, a small amount of ferric chlorid. In the presence of hydrocyanic acid, ferric thiocyanate is produced.

ATROPIN AND SCOPOLAMIN

The contents of the stomach are filtered and extracted with chloroform or benzin. By evaporating the extract, which will produce mydriasis when introduced into the eye.

CHLORAL

The contents of the stomach are re-distilled at 60° to 65°. Chloroform is formed by the following reaction: To the distillate add sodium hydroxid. The intense penetrating odor of chloroform is characteristic.

form vapor may be led through a heated tube into a solution of starch and iodine. The free chlorine formed by heating the chloroform liberates iodine which produces blue iodine of starch. Chloral hydrate may be extracted from gastric contents by ether. In this method, which involves the conversion of chloral hydrate into chloroform, preformed chloroform must be excluded by the reaction performed before distillation. Chloral hydrate may be removed from the gastric contents with ether, and may subsequently be detected in the residual residue after evaporation by dissolving the residue in water and adding ammonium sulphide. A brown precipitate is formed, and an unpleasant and irritating odor is developed.

POTASSIUM CHLORATE

A solution to be examined is made distinctly acid with sulphuric acid, and indigo is added. On adding fuming sulphuric acid, and finally, a solution of sodium sulphite. The color of the solution is changed to green or yellow. The potassium chlorate is separated from the mixture by dialysis, and the substance detected in the

OPIUM

The presence of opium may be suspected from the characteristic odor and the result in the case of laudanum administration. The detection of opium and the exact methods will be found in Witthaus and Becker, System of Legal and Toxicology.

PHOSPHORUS

Investigation should take place with as fresh materials as possible. The contents containing it are often phosphorescent in the dark. The substance may be detected by the following methods:

Lead's Method.—The contents of the stomach are shaken with a little lead acetate solution, to remove hydrogen sulphide, and the mouth of the flask closed with paper moistened with silver nitrate solution. The whole is allowed to stand in the dark for some time. With traces of phosphorus, the paper is stained

Perlick's Method.—The contents of the stomach are made acid and distilled in the dark. The condenser will contain a luminous ring. Small amounts of ether, and oil of turpentine, which may be present in the contents of the stomach, will prevent the reaction.

Blondlot's Method.—This method is based on the fact that small quantities of phosphorus render a colorless hydrogen flame distinctly green.

MERCURY

Detection may be made with brass gauze, but it is necessary first to destroy the other substances in the mixture. This is done by the method of Fresenius. To the contents of the stomach are added $\frac{1}{2}$ to $\frac{1}{3}$ the volume of concentrated HCl and 20 gm. of potassium chlorate. The mixture is heated in a porcelain dish in a water-bath, and at intervals of from five to ten minutes 0.5 to 2.0 gm. of potassium chlorate are added, until the liquid is clear and of a straw yellow color. Potassium chlorate is also added from time to time. Two gm. of chlorate are again added, allowed to cool, and strained through a cloth. The mixture is heated on the water-bath until the smell of chlorine has disappeared. The liquid can now be tested with brass gauze. In most cases of poisoning with mercury the substance is sublimate. This is soluble in ether, and may be directly extracted from the residue with ether. On evaporating the ether the crystals of sublimate residue may be identified by the red precipitate given by potassium iodide, which is in excess of the reagent.

STRYCHNINE

A solution is made alkaline with ammonia, and extracted with benzol. The test can be applied to the residue. Frogs injected with the solution are killed with tetanic convulsions. Only 0.005 mg of strychnine are necessary to produce the result. Chemically, the substance may be detected by extraction with ether. The residue a drop of sulphuric acid is applied, and a minute crystal of potassium bichromate added. In case strychnine be present, a violet color is pro-

EXAMINATION OF THE

Inspection, palpation, auscultation, and their help in the examination are considered upon pp. 368 et seq., 371 et seq., and 277 et seq.

Hence, we will now discuss only the digital and speculum examinations, and the examination of the feces.

LOCAL EXAMINATION

DIGITAL EXAMINATION

The examiner ordinarily employs the index finger, and, of course, with a carefully cut nail. It is better, however, by employing the ordinary thin index finger. Obstetricians do well to employ a finger with a nail. At the proximal end of the finger as the patient lies on the dorsal decubitus with the legs widely apart, the rectum of the back (the latter is advisable, as it does not prevent his palpating the anterior abdominal wall). If more convenient, we examine with the patient on the knees. The knees should be well drawn up, the arm in all directions. The knee-chest position is so frequently employed by the gynecologist, as it displaces the intestinal coils upward and forward of the pelvic viscera. For different positions these positions can be varied, but the important thing is that the entire rectum be palpated, and we must be able to do so if possible. The anal opening should be examined by digital examination, as we can thus detect hemorrhoids, prolapsus, fistula in ano, etc.

Separating the folds of the buttocks, the finger should be introduced slowly and carefully so as not to cause pain or injury. If the finger is not following the axis of the rectum, especially when they try to palpate the rectum, they will then fail to reach up very far, and may have found a stenosis, though no stenosis exists. The rectum should be remembered. The direction is first a little forward, then backward into the hollow of the pelvis toward the sigmoid flexure. When the finger is introduced, remember to keep it always in the mucous membrane. If feces be present, the direction in which to advance the palpating finger may reach deeper. The examiner's thick, short fingers and the obstacles. Sometimes the pain of

ion of the external sphincter will prevent an effective examination. Only in exceptional cases is it allowable to introduce two fingers. Introduction of the whole hand under anesthesia (after Simon) has, as we know, been discarded as too dangerous a method.

Digital examination reveals, first of all, the more crude anatomic changes—carcinoma of the rectum, other tumors and ulcerations of the rectum, polyps, which are not situated too high up, an invagination which has reached down as far as the rectum. Large internal nodular masses may also be felt; but unless thrombosed, it requires considerable experience to differentiate them with certainty from the normalities and folds of the rectal mucous membrane. Superficial changes are quite as difficult to appreciate by palpation.

In the case of intestinal obstruction, *considerable distention of the abdomen* points strongly to fecal rather than some other type of intestinal obstruction. If fecal masses have pushed down into the rectum and the symptoms of obstruction have improved, our prognosis immediately becomes more favorable, even before any feces have been evacuated. An extremely painful digital examination would suggest inflammatory changes of the rectum. If slimy, purulent, or bloody masses adhere to the finger when withdrawn, this diagnosis is still more strongly confirmed. A microscopic examination of the material adhering to the finger will sometimes aid in the diagnosis of tuberculous or inflammatory changes, and perhaps be more serviceable than the examination of the feces, especially if the rectum has been just cleaned of fecal matter by an enema (pus, tubercle bacilli, amebæ, oxyuris). (Compare Examination of Feces, p. 510.)

Digital rectal examination is important in diseases of the nervous system. The degree of impaction in the rectum, the sphincter tonus, the sensitiveness of the rectal mucous membrane tell of the condition of the rectal activity (function). This information is the more important as the character of defecation and the shape of the stools depend not only upon the rectal innervation, but upon the influence of the brain above.

In examining the rectum we must also try to obtain information regarding the condition of the adjacent organs: the prostate and seminal vesicles in the male, the uterus, tubes, and ovaries in the female. In a virgin, as a rule, a pelvic examination can be successfully accomplished only by way of the rectum.

EXAMINATION WITH THE SPECULUM AND WITH THE PROCTOSCOPE

With the aid of a so-called rectal speculum the examiner can see the inner surface of the rectum directly. Rectal specula are made quite like vaginal specula, bivalve, duck-bill-shaped, or many valved. They may also consist of separate spoons. The speculum should first be warmed and well oiled, and then carefully introduced into the axis of the rectum. With an ordinary speculum a good light can be reflected, and the rectal mucous membrane at the point of introduction carefully examined. The position of the patient will be varied according to the part of the rectum to be examined, either the lateral, the usual gynecologic position, or sometimes the knee-chest position. The advantage of the knee-chest position is that the rectum is relieved by the intestines dropping and so is more accessible to examination. In difficult cases the speculum examination should always be tried in this position and with the pelvis elevated. The speculum should be introduced very carefully and slowly. The many-valved speculum must be furnished with an obturator before being introduced, and also before its further advance, for otherwise they are apt to pinch and injure the mucous membrane.

Examination with a speculum is difficult on account of the limitation of field of vision, and the fact that the parts are usually in an abnormal position under abnormal tension, so that the interpretation of the findings is difficult. Prolapse of the rectum is often caused by the irritation of the speculum, especially in inflammatory affections, so that it is very difficult to adjust the instrument. Examination reveals many of the changes, but others most essential to determine inflammation as inflammatory congestion and superficial ulcers which are not palpable, are very difficult to recognize with this instrument, for its pressure causes considerable congestion, altering the color, and in the case of ulcers oftentimes brings on hemorrhage, which covers the field of vision again and again even if sponged off carefully. In these conditions severe pain usually interferes with the examination. The tubular and the many-valved specula frequently furnish incorrect conclusions because the mucous membrane prolapses within the instrument in irregular folds. The bivalve, duck-billed specula, by means of which a part of the membrane smoothly stretched can be exposed to view, are rather better. The examination is most conveniently made in the knee-chest position, with the instrument consisting of two separate spoons, but its employment always requires the aid of an assistant.

The results of the ocular inspection of the rectum have been essentially improved since we have employed modern proctoscopy (see below).

MODERN PROCTOSCOPY, EMPLOYING ELECTRIC ILLUMINATION AND A DEVICE FOR INFLATION¹

Inspection of the rectum plays an important part in diagnosis since we have substituted for the ordinary rectal specula, whose limitations have been discussed above, the much more reliable rectoscopic instruments perfected by the efforts of Otis, Kelly, Pennington, Laws, Tuttle, and H. Strauss, and since Schreiber's² experimental studies have placed the methods of rectoscopy upon an exact scientific basis in accord with anatomic, physiologic, and clinical observations. H. Strauss' so-called proctosigmoidoscope³ is the most complete and valuable rectoscope. (See pages 212 and the following pages.) It consists of a straight metal tube, 35 cm. long and 2 cm. in diameter. It is constructed on the principle of an endoscope, and has an electric lighting attachment. The great length of the tube is an important feature for it can be introduced into the rectum like a speculum, affording, under favorable conditions, a view 30 or more cm. above the anus. This great length is made practicable by the connection of the interior of the tube with a rubber bag to inflate the rectum with air during the introduction of the instrument and after it is in place. A glass plate closes the outer end of the tube when in use, making the inflation possible. By this means introduction of the instrument in spite of the varied curvature of the bowel, is facilitated, since further advancement is aided by the examiner and the tip of the instrument pushed in as the latter becomes visible through the glass. The tube is marked in centimeters so that the depth of insertion is represented. The proctoscope tube with its handpiece and obturator which closes the inner end before introduction of the electric light which is fixed in the interior of the tube by means of a fastening shown in the accompanying illustration of the inner opening of the tube. The dotter is attached to the apparatus in the tube. The fastening of the dotter is mentioned above, with a bayonet joint. This arrangement permits visual examination while the rectum is inflated. The rectum should be introduced so that the lamp is up close to the mucous membrane, likely to be smeared with feces, which, if pressed against the tube. For operative purposes and for enlarging the field of vision it is, of course, necessary to remove the tube easily accomplished by loosening the bayonet joint. The tube itself can be removed with forceps for freeing the visual field are furnished for use are as follows:

³ Made by L. and H. Lowenstein, Ziegler.

the evening before examination the patient receives an enema of 1 liter, and three hours before, another of $\frac{1}{2}$ liter, of physiologic salt solution. Care should be taken that the enema is completely returned. If diarrhea exist, 10 to 15 drops of opium are given one hour before the operation.

The patient is always placed in the knee-chest position, with his head in contact with the table and his legs spread somewhat apart.

The instrument with the obturator in position, is first warmed and then lubricated. The patient's anus should also be smeared with vaselin. It is rarely necessary to use cocain, eucain, or anesthesin ointment.

The introduction of the instrument as far as the sigmoid is carried out in three stages.

Through the perineal portion of the rectum (about 5 cm.), the tube with the obturator in position is held approximately horizontal.

Through the ampulla of the rectum (about 6 cm.), the obturator removed and the tube in place, the tube is guided by the eye. The part of the tube within the rectum is tilted upward.

Fig. 211 —Strauss's rectoscope.

Through the introitus flexuræ. The assistant now holds the instrument at the handle, while the examiner, guided by his eye, brings the tube into a horizontal position. A slight lateral movement or one from above should now disclose the entrance into the flexure; but if not, the window of the rectoscope and the assistant inflates the bowel with one or two bulbfuls of air while the examiner watches for some movement of the bowel-wall to disclose the entrance into the flexure for bubbling murmurs.

The instrument may now be very gently pushed further into the flexure, guided by the eye, by carefully lifting the outer end, and, if necessary, by inflation.

Hard or solid feces which obstruct the field of vision may either be pushed away or wiped away.

The character of the mucous membrane is to be noted during the introduction and withdrawal of the instrument.

The knee-chest position recommended by Strauss, though convenient for the examiner, is naturally unsuitable for many patients. In such cases the author has found it convenient to employ the lateral or gynecologic posture. If the latter be employed, the patient's pelvis must project well beyond the edge of the table, to permit

depressing the outside end of the tube due of course, work in an uncomfortable position.

Since the introduction of Strauss's rectoscope, noted a distinct advance in the accuracy of view obtained with ordinary rectal specula. The account of prolapsed folds of mucous membrane in view into a stretched open cavity on the withdrawal of the instrument, not the slightest chief advantage is, however, that it enables one to examine 30 cm. of the lower bowel, and to see while digital examination cannot extend further. The ordinary rectal specula little further improves the prognosis of rectal carcinoma. Every practical man, because it is easy to handle and requires no special apparatus, should have one at hand, a head-mirror answer.

Besides aiding in the diagnosis of rectal disease, the rectoscope is very useful in recognizing other conditions not accessible to palpation and which include hemorrhoids and anemia; the existence of an intensely inflamed area responsible for obscure bleeding, benign growths, the impression of malignancy (Schreiber's rectoscopy), oxyuris infection. This writer has determined the position of the sigmoid above the angle of the sigmoid at the junction of the upper and lower loops of the rectum, even if Kuhn's spiral sounds are used.

The reader who wishes to employ the rectoscope should do the fundamental work on rectoscopy. The following are important statements upon the anatomy of the rectum. The series of interesting rectoscopic pictures will be found in the text. The author quotes the following anatomic data: The rectum above the anus; from there the descending colon (rectoscopy) stretches to 32 cm. above the anus into the perineal or sphincteric portion and the internal sphincters, with the so-called internal sphincter. The external sphincter is characterized by longitudinal fibers. The perineal portion of the rectum is 2 cm., the internal 2.5 cm. A fold of the rectum, in which two constant folds are found, the upper plica sacralis (inferior). The plicae are sometimes to the right, sometimes to the left. The ampulla is divided from the rectum by the right. The plicae sigmoidea situated above the rectum; they vary in number and usually from 1 to 3. A fold of mucous membrane which forms the sigmoid generally prevents the advancement of the rectoscope into the anus.

INSUFFLATION (RECTOSCOPY)

Inflation of the rectum is best accomplished by Davidson's syringe.¹ It aids in determining the position of the rectum and of the colon. When inflated, they can be felt as a firm abdominal wall, separate from the rest of the abdomen by percussion and palpation. The position of the rectum in relation to their origin in the colon, the sigmoid, can often be determined by the aid of the rectoscope. The condition of the rectum itself, the sigmoid, can be determined. For moderate stenoses—which are not usually accompanied by obstruction—offer no obstruction to inflation, while severe stenoses can be easily enough diagnosed without determining the seat of such obstruction. A considerable quantity of air into the rectum, if the rectum is situated low down. This, however, if the stenosis is pronounced, there will be so much abdominal distention of the rectum even if the obstruction is not complete.

food (see p. 505); but the diets do not consider the influence of the food which may remain in the intestine (see above p. 542 for the demonstration of this). The clinical examination of the character of the feces is as yet impracticable (of the feces, see p. 532). Even the determination of the utilization of the nutrients of v. Noorden¹) furnishes no information of the latter alone, and the determination of the motility of the digestive tract is not justified in deducing from the degree of metabolism, nor the place in the organism. (See p.

EXAMINATION OF THE INTES- TINAL GLUCOSE

For a long time the writer has had no direct evidence in regard to the character of the reference to proteid digestion. For capsules, which are made from gelatin, either do not dissolve in the gastric juice but they are rather quickly soluble in the place of Unna's keratin-coated pills. Glutoid capsules may be utilized to determine the pancreatic function. They diffuse through the capsule-wall, and the examination of the saliva or the urine for this purpose. Iodoform has given both from the stomach and the intestine in a quarter to one and one-quarter hour a marked iodine reaction can be observed in the former) with chloroform, Iodoform has another great advantage.

Salol answers very well for the determination of the iodine reaction. Half an hour after the ingestion of 0.5 gm. in the urine with ferric chlorid as a test after the glutoid capsule has been dissolved the iodine reaction will be demonstrable in the saliva in a quarter hour if 0.15 gm. of iodoform and the salicyluric reaction can be demonstrated half an hour after the administration of salol.

In order to make the conditions of time that the capsules remain in the intestine without digestive stimulation it is advisable to fast (p. 444). The author's experi-

¹ Grundriss einer Methodik des Stoffwechsels, Berlin, 1893; Zeit.

³ Filled glutoid capsules of various sizes. A. G. Haussmann, in St. Gall, Switzerland, and their constancy is guaranteed. The capsules must have a certain minimum hardness is requisite. For the purpose for which they are to be used. The diagnostic capsules which are used for use in children capsules are pretest capsules with 0.05 gm. iodoform. The latter must be administered at salol. The following statements in regard to diagnosis.

possible, normal gastric motility, normal intestinal digestion, and normal absorption, the iodine reaction may be expected to appear in the saliva and the salicyluric reaction in the urine, in from four to six hours. To reliability of the capsules obtained from the manufacturer it is necessary to test the reactions are obtained in this length of time in healthy individuals. Four hours after the administration and at regular intervals thereafter the expectorates saliva or, better, voids urine¹ in numbered beakers. These are examined later for the presence of iodine or salicyluric acid, according as mentioned on pp 434, 610, and 611. The author has found that iodine in the saliva is so irregular in many individuals that he recommends the urine test in preference unless the patient cannot retain his urine or his urine is deeply colored by bile-pigment. The time of voiding the specimen which exhibits the positive test shows the rapidity with which the glutoid capsule is dissolved, i. e., the intensity of the pancreatic digestion (see certain restrictions later). Only rough, approximate differences in the time of the reaction of diagnostic importance, so that it is really sufficient to examine the saliva or urine at six, eight, ten, and twenty-four hours. To make the test as uniform as possible it is perhaps advisable to administer the capsules in the morning with breakfast, upon an empty stomach, and then four hours later allow the patient to eat as usual. The specimens of saliva and urine may, of course, be saved and examined afterward.

In drawing conclusions in regard to the intensity of the pancreatic digestion, must, of course, be sure that within six hours the capsules are dissolved by the gastric juice nor by any chemical agency in the intestine other than pancreatic secretion. The author has proved that this is so by showing that capsules can resist a strong gastric digestion for at least seven to eight hours, without refractive changes in the intestine for twenty-four hours. When they are introduced, together with an Ewald test-breakfast, into a stomach with normal motility they do not remain in the stomach much longer than one hour, but swell up with gastric contents and are readily floated through the pylorus. Before a delay in digestion can properly be attributed to defective intestinal digestion the gastric motility must be tested and proved to be normal by withdrawal of a test-meal and lavage. For this no method of gastric examination is adequate unless the stomach-tube is not employed. If there be motor insufficiency of the stomach a retarded reaction is to be ascribed to the delay of the capsule within the stomach, whether it has been dissolved there or, later on, in the intestine. Individual differences in the rapidity of the excretion of the iodine and salicyluric acid, in consideration of the test's duration, are not responsible for any considerable delay in it because experiments have shown that, even in functional kidney disease, as soon as these substances get into the circulation the reaction appears in the saliva very quickly. On the contrary, another factor in the experiment is the rapidity with which the iodoform is absorbed after the capsule is dissolved by the pancreatic juice. The glutoid capsule test gives us, therefore, a resultant of the power of the pancreatic digestion and the absorptive power of the intestine. If we wish to determine the latter alone, we can repeat the test on another day, when we are sure that the saliva no longer gives an iodine reaction (nor the urine a salicyluric acid reaction), administering the iodoform (or salol) in an empty capsule with a glass of water on an empty stomach. From von Mehring's experiments it is fair to assume that under these conditions the stomach empties its contents rapidly into the duodenum and that thereby most of the salol and iodoform, with the weight of the latter, is hurried along into the intestine by the rapid passage of the water. According to these experiments, moreover, absorption always takes place rapidly (see above) that the results of the glutoid test depend almost entirely upon the sufficiency of pancreatic digestion, provided gastric motility be normal.

The results obtained from this method of examination are interesting. Even in cases where the stomach-contents contained no free hydrochloric acid or pepsin, the reaction was not delayed so long as the gastric motility was good. The remarkably good nutrition of such patients, and the result of such a test, prove that the pancreatic digestion may perform vicariously the entire gastric function. In cases of constipation, due only to an increased peristalsis, without any marked disturbance of intestinal digestion, the reaction is either normal or even somewhat hastened, due to the favoring influence of increased motility. In other types of diarrhea, characterized by an involvement of the intestinal chemistry or intestinal absorption, the reaction is either absent or distinctly delayed. In the latter case the results are so evident that the patient should completely empty the bladder each time.

usually stained strongly with bile. We can prove that it is duodenal by rating a typical proteolytic, lipolytic, and diastatic action (see below). Following Boldireff's physiologic experiments on dogs, Volhard¹ has shown that there occurs a regurgitation of pancreatic juice and bile into the stomach when a large quantity of fat be ingested, and that with an oil breakfast it is possible to obtain pancreatic juice, with or without bile from the stomach. He introduces olive oil through a tube. One-half hour later he withdraws what represents generally 50 to 100 cc. of oil, together with a watery, mucoid, often greenish fluid which can be readily separated from it either by the use of a pipet or of a siphon-funnel. The advantage of this over the Boas method is perhaps that the pancreatic juice obtained in this way is more constant and probably of a physiologic character, corresponding to the stimulation employed. Volhard was able to demonstrate tryptic action in 86 per cent. of his cases by the casein method given below. Although these procedures must not be considered as entirely irreproachable for testing the intestinal functions, because the conditions do not quite correspond to the physiologic requirements, nevertheless Boas' and the preference of Volhard may be depended upon to diagnose the presence of pancreatic juice, the patency of the pancreatic duct, just as well as the employment of capsules (p. 506). A quantitative estimation of the tryptic power of such an "oil juice" must be made with some caution because trypsin is obviously altered by gastric juice and because a partial alteration cannot be excluded, since the "oil juice" has an acid reaction due to the admixed gastric juice. It would be interesting to determine whether the regurgitation of the pancreatic juice into the stomach in Volhard's method is to be considered a physiologic procedure conforming to the principle of adaptation (transference of the fat digestion to the stomach), or a sort of pathologic appearance induced by fat ingestion. The demonstration of tryptic action in the pancreatic juice obtained in this way is easy; but the demonstration of lipolytic and of the diastatic enzymes has not yet been always successful. For estimation, the fluid must, if necessary, be rendered distinctly alkaline as far as possible by the addition of a weak sodium carbonate solution (so as to prevent any of the trypsin being destroyed by pepsin). Trypsin can be most easily demonstrated by digesting in the alkaline fluid, at incubator temperature, a flake of fibrin stained with Magdala-red. The fibrin, which is dissolved by the tryptic action, colors the fluid red.

Thus and Huber² have announced another method for demonstrating the activity of trypsin. Fresh fibrin is prepared by whipping freshly drawn horse blood, and washing the coagulum with water until it becomes colorless. It is finally completely covered and allowed to stand for twenty-four hours at 40° C., in a 1 per cent. solution of sodium fluorid, then filtered. We thus obtain a solution of fibrin in sodium fluorid which will keep for months. The fluid which is to be used for trypsin is first diluted with an equal volume of a 2 per cent. solution of sodium fluorid, and one volume of this dilution is added to two or three volumes of fibrin solution, and the whole mixture digested for a considerable time at 40° C. If trypsin be present in the fluid, crystals or crusts of tyrosin will form on the walls of the vessels. The crystals may often be recognized by the naked eye. In addition to their crystalline shape (see Fig. 240) they are characterized by their appearing as dark spots on a dark background in the polarizing microscope (with crossed prisms). The advantage of this procedure is that the digestive mixture remains sterile for an unlimited length of time, owing to the antiseptic qualities of the sodium fluorid. For the qualitative as well as the quantitative testing of the tryptic action of the "oil juice" Volhard employs the alkaline casein solution, prepared for his method of estimating pepsin. (See p. 468.) He permits digestion in the mixture, which has been divided into two long-necked digestion flasks, like those in the method for estimating pepsin, and placed in the water-bath, and then proceeds in the same way as in the estimations. After acidulating, he precipitates the undigested casein with sodium sulphate, filters, and titrates the filtrate. He then compares the acidity of that of the mixture which, save for digestion, has been similarly treated, and makes a proportion between the increase in acidity and the amount of the trypsin of digestion. (See p. 468 et seq. for the principle of the method.) The procedure is as follows: "100 cc. of the alkaline casein solution are measured off in two digestion flasks (see p. 468), chloroform water is added up to the 300 cc. mark; the "oil juice test" are added to one flask, while the other serves as a control. The flasks are placed in a water bath; the temperature is kept at 40° C. by means of a thermostat regulator, and the contents are allowed to digest for from one to twenty-four hours. Eleven cc. of normal HCl solution are then added to each flask until all the acid is neutralized. (Zentralbl. med. Woch., 1907, No. 9. ² Arch. de Physiol., 1894, p. 622.)

the precipitated casein is again dissolved. The addition of a 20 per cent. solution of sodium up to the 400 cc. mark. The mixture is then shaken to 400 cc. by the addition of more sulphate so suring glass, and 200 cc. of the filtrate are titrated with $\frac{N}{4}$ sodic hydroxid solution. The difference in measure of the tryptic action." By this method Vialow's law of geometric proportion cannot be applied but rather a law of arithmetic proportion. They are proportional to the amount of juice employed of the filtrate in the procedure be represented the fraction $\frac{a}{f}$ is a constant. Müller serum plates to demonstrate tryptic action.

Grützner-Gamugée recommended the following activity: An emulsion of 10 parts of oil, 5 parts prepared; also a neutral solution of litmus, which appears violet against white paper. Ten cubic centimeters and 5 drops of the emulsion are placed in equal quantities (e. g., 2, 4, 8, 16, and 32 drops) of the successive test-tubes. They are then immersed. After a few moments the different tubes are removed. When present, the color of the fluid will have changed of solution added. For further tests see *Hare's Chemistry*, translated by Mandel, fifth edition.

To demonstrate diastatic action, increasing amounts are added to a thin starch paste. If a milky mixture and no violet color appears (no diastatic action has taken place. Again, the Trommer's test, will prove the same thing. (See tablets (see p. 542) may also be used.

EXAMINATION OF

Introduction.—The author emphasizes the importance, and urges the general use of water-closets which can be readily observed by the patient.

FREQUENCY OF MOVEMENTS; DIARRHOEA OF FECE

There is considerable variation in the movements even in health. Some absolutely normal movement of the bowels only once in two or three days. There is no sharp line of demarcation between the pathologic and physiologic conditions usually restricted to a condition of infrequent movements associated with certain other difficulties or diseases in relation to the quantity of food taken. Diarrhea is employed only when the movements are not only frequent but also liquid. Infants normally have movements every twenty-four hours.

Other things being equal, the frequency of movements upon the amount of nourishment ingested. In the number is reduced to a minimum; in diseases a more or less complete state of constipation. For instance, an individual who vomits frequently. In the same way a gastric case of

¹ Consult J. Schmidt and J. Strassburger, *Diagnose*, 1901.

takes little on account of lack of appetite or because he cannot do anything, is to be considered as a case of starvation.

Diseases which give rise to *constipation* are: gastric and intestinal diseases (especially chronic), gastric dilatation, intestinal obstruction of various sorts, peritonitis, meningitis, and other diseases which increase intracranial pressure. Sometimes constipation becomes a more or less independent malady (chronic constipation), which is referable to a great variety of causes.

Complete absence of movements is generally characteristic of some kind of intestinal obstruction. Not infrequently, however, fecal material may be evacuated some time from the section of the intestine below the obstruction. Continuous evacuation is characteristic of some types of obstruction, especially of invaginations, complete axis rotations, or of certain strangulations. But these movements are not fecal in character; they consist of serous or, often, bloody masses from the lower intestinal segment, due to the venous congestion at the seat of obstruction. Their character and sometimes the absence of the passage of gas which is in marked contrast to the presence of formed or fluid movements should be sufficient to justify the diagnosis of obstruction.

Diarrhea occurs in acute and chronic gastric and intestinal catarrh, in certain types of chronic peritonitis, in intestinal tuberculosis, intestinal atrophy, intestinal degeneration, cirrhosis of the liver, cholera, typhoid fever, and many other infectious diseases, and uremia.

The daily quantity of the feces passed, other things being equal, is very proportional to the amount of food ingested. The volume of the individual movements is generally inversely proportional to the number. There are, however, numerous exceptions to the last two statements, e. g., in patients who vomit, often much less is evacuated in the movements than is ingested. Again, in severe forms of diarrhea, especially cholera, much more is evacuated than is ingested, because, in addition to the food residue, there are the secretions and exfoliation of the intestinal mucous membrane. The admixture of blood may also increase the quantity of the feces.

In diarrhea the individual movements vary in volume and frequency according to whether the disease is localized in the upper or lower intestine. In diseases of the lower part of the colon, of which dysentery is a typical example (rectal diarrhea), the individual evacuations are not very voluminous but they are very frequent, on account of the continuous reflex irritation. In diseases of the upper intestine each evacuation is more copious, but they do not occur so frequently (e. g., typhoid), because there is not the same persistent desire to empty the rectum. These, so-called "profuse" diarrheas may be found in involvement of the entire portion of the colon as well as of the small intestine.

After a period of marked constipation quite incredible quantities of feces are often passed.

CONSISTENCE AND SHAPE OF FECES; STRATIFICATION OF LIQUID MOVEMENTS

The normal consistence and shape of feces is well known. The content is hard in constipation, fluid in diarrhea. Between these extremes are all sorts of intermediate forms. The small fecal balls, like scybala, which occur in intense constipation, from the tightly packed fecal matter becoming friable, are especially noteworthy. On the other hand, scybala may be of very unusual volume in constipation if a large quantity of feces stagnate in the rectum and distend it mechanically.

In intestinal stenosis but a short way have a diminished transverse diameter their shape changes again below the justly called attention to the fact that masses may be found also in inanition (spasm of sphincter).

Very liquid diarrheal movements liquid constituents in an upper layer lower. Frequently, however, the feces an admixture with urine.

COLOR AND GENERAL APPEARANCE

The normal color of the stools color is not due to biliary pigments (urobilin, etc.). Infants' stools are yellow, because they contain unaltered

The color of the feces varies more or less. A milk diet and much fat gives a light color. Red wine, blueberries, blackberries, or blackberries give a dark color. Food rich in chlorophyll (vegetables) produce a green or olive shade in the stool. Cocoa, causes a noticeable red-brown color of the feces. Extract of logwood produces a black color. After the employment of rhubarb, senna, or other purgatives, a pronounced yellowish-brown color is observed. If iron be added, the shade is more nearly red. In cholera, the stools are blackish. According to Wassilieff and Hoppe-Seyler, the formation of sulphur compounds of mercury, and the antiseptic action of the calomel, which transforms the pigments into urobilin, and also to the sulphur, which changes the bilirubin to biliverdin. (See p. 100.) Stools are generally of a blackish color. Quincke has observed the formation of metallic sulphur, as was found in the case of a reduction of the bismuth salt to bismuth sugar. Not infrequently bismuth stools are observed after calomel, a phenomenon which Quincke also checks the transformation of the bile. Contrary to the general belief, the stools are not black, but ferrous sulphate. He maintains that immediately after the stool has an abnormal color, and certainly not black, but only after standing and only upon the surface. This phenomenon is due to the oxidation of the ferrous sulphate to the air. Patients to whom we administer colored stools there is often an admixture of blood. It is generally easy enough to distinguish blood in the stool. The author has observed a case of icterus in which the stools, as a result of a cholelith, exhibited a peculiar dark-gray color. After the administration of methylene-blue the stools go on in the intestinal canal itself. The color of the ordinary color, due to the reduction of the methylene-blue, moments they become bluish green on the surface of the mass. If the stool be preserved in alcohol, it remains of the ordinary color.

Chromogenic bacteria may also produce green pigment have been found. The author has seen a marked violet color of *Bacillus pyocyaneus*. He was able to establish its chemical identity.²

¹ Münch. med. Woch., 1896, No. 36.

² See H. Girard, Zeit. f. Chir., vol. vii, cyanin.

pathologic conditions the stool may be abnormally colored in addition of blood. (See p. 514 et seq.) The stool is abnormally colored in *acholia* (deficient production of bile with absence of bile and in retention of bile due to occlusion of the biliary passages, etc.). Such stools present a peculiar grayish-white appearance (pale). This is due not only to the deficiency in amount of bile, but also to an abundance of unabsorbed fat.

Nothnagel¹ distinguishes uncolored feces from acholic stools. The former are only without any icterus, but, in contradistinction to the latter, without any noticeable disturbance of fat-absorption. Nothnagel and von Jaksch suggest that in these cases, instead of urobilin, colorless reduction products are formed from bilirubin (Nencki's leucourobilin, urobilinogen). This subject has yet been very closely studied from a chemical standpoint. Nevertheless, the possibility is certainly suggested, because von Jaksch succeeded in extracting with alcohol very considerable quantities of urobilin from such so-called acholic stools (p. 583), and because such stools often darken considerably when exposed to air, an effect evidently to be ascribed to oxidation. This may be termed acholic. Quincke claims that the normal color of such stools is reproduced when ferrous sulphate is administered, merely because the latter inhibits the reduction of urobilin, which is ordinarily caused by putrefactive processes in the intestine.

In diarrhea the movements are, generally speaking, light colored, but the pigment is distributed through a much larger volume, but in some cases (especially in intestinal catarrhs) they may contain the bile-pigment and vary in color from green to yellow. (See p. 575 et seq. for demonstration of bile-pigment in the stools.) The presence of unabsorbed bile-pigments in the stools is always pathologic, except in infants with diarrhea.

Sometimes find undigested food-particles in the stools. This is of diagnostic significance so far as indigestible constituents are concerned, such as seeds, stones, and the skins of fruits. But if the stools contain considerable macroscopic evidence of substances which are not so changed by the intestinal digestion as not to be recognized (such as meat, flakes of casein, etc.), we naturally attribute this to some digestive disturbance. This condition, found in various intestinal disorders, was formerly described as "lientery." It is due to a fistulous communication between the stomach and intestine, or to a loop of the upper and a loop of the lower intestine, more or less distended with undigested food will appear in the stools. (See p. 529 et seq. for microscopic examination of the stool with reference to the condition of the food.) If excessive decomposition processes take place in the intestine, the diarrheal movements will exhibit a peculiar character. In infantile diarrhea the stools are often of a greenish color due to the abnormal decomposition of the bile-pigment: or, if there are many flakes of undigested casein, they may have a granular appearance instead of their normal smooth appearance.

Reference to the admixture of mucus, blood, and pus in the stools is given in the following pages.

ODOR OF THE STOOLS

The odor of normal human feces is well known. It is due chiefly to skatol, and perhaps also to methyl mercaptan. The fecal odor is much more pronounced upon a meat than upon a vegetable diet.

¹ Die Erkrankungen des Darmes und Peritoneums, p. 18.

from the color and distribution of the blood admixture. For example, solid feces coated externally with blood would indicate a hemorrhage only in the lower portion of the intestine, where the feces are already solid and formed (hemorrhoids). Conversely, solid feces tinged throughout would point toward a hemorrhage in the lower or the upper part of the intestine. Even in liquid stools the admixture of blood is usually more intimate if the hemorrhage be in the upper part of the intestine. But the liquid movements from the lower intestine (dysenteric meat-juice stools, see p. 540) may also contain finely mixed blood. The color of the blood in liquid stools sometimes forms a good criterion for determining the seat of hemorrhage. The higher the hemorrhage is, the more altered is the original blood due to intestinal putrefaction and intestinal digestion (transformation of the hemoglobin to methemoglobin and hematin). In hemorrhage from the stomach, gastric digestion may also cause some changes. Profuse hemorrhage from the stomach does not always cause hematemesis, so that we may first suspect the condition from the appearance of the stools, which may be nearly black and of a tar-like consistency. Profuse typhoid hemorrhages sometimes show an alteration in the blood; usually, however, it is still distinctly red, because it comes from the ileum, and a stool follows a hemorrhage quickly. Watery, serous diarrheal stools without true fecal matter are of diagnostic importance in certain types of ileus, especially invagination (See p. 511.) (See p. 540 for other peculiarities of certain diarrheas characterized by blood in the stools.)

The diagnosis of obscure cases of carcinoma and of ulcer of the stomach and small intestine has been materially assisted by the demonstration of so-called occult blood, i. e., the slight but generally constant admixture of a very small amount of blood demonstrable only by chemical test. Boas has recently emphasized the importance of this occurrence. In the color of the stool there is often nothing to suggest the presence of blood. The author once saw a case of icterus due to carcinoma of the gall-bladder in which occult blood was always present in the acholic stools which exhibited a pale yellowish color without a suggestion of a tinge of blood.

In doubtful cases a microscopic examination may determine the presence of blood in the feces; but the red blood-corpuscles are often considerably changed and hard to recognize. Sometimes they are destroyed completely, and then the question as to whether blood is present must be decided by a chemical or spectroscopic examination. (See p. 544 et seq.)

PUS IN THE STOOL

Conclusions similar to those discussed under blood in the stools may be drawn from the different ways in which pus is mixed with the fecal material. A very considerable admixture of pus or pure pus stools may be due to perforating abscesses. A slight amount of pus in the stools, which often can be demonstrated only microscopically (polynuclear leukocytes), and which is frequently associated with blood or mucus, may be due to catarrhal changes, but is generally due to ulcerations or abscesses of the mucous membrane (tuberculosis, dysentery, etc.). The presence of pus indicates an ulcerative process. It may be very difficult to demonstrate pus in the stool, because the pus-corpuscles are sometimes destroyed by duodenal digestion and putrefaction in the colon.

Experiments bearing directly on this point show that intestinal decomposition may destroy polymorphous nuclei in a comparatively short time, so that it is impossible to find polymorphous nuclei may resist the decomposition for a long length of time, but they are difficult to recognize, especially as they break into fragments in the same way from the cell nuclei of any animal food during digestion. Moreover, even in normal stools leukocytes may be found as a result of their passage through the mucous membrane. The demonstration is difficult, even in perforation of perityphlitic abscess, because decomposition in the abscess has the character of the pus, and this change is still in progress.

The undigested lumps of casein found in the milk diet must not be confounded with shreds of fecal pigment, the former sometimes assume a form which can easily be recognized microscopically by the fat-drops.

TUMOR FRAGMENTS IN THE STOOL

Larger or smaller pieces of tumor are not infrequently found in the rectum or of the intestine higher up. These fragments are found in a liquid stool by their grayish-red color and soft consistency.

As it is often impossible to recognize the finer details of the tumor fragments, the essential point is to detect the numerous nuclei of the cell constituents and without the cell walls which latter usually resist putrefaction. Fragments of tumor are sometimes found in the stools. They may occur in the neighborhood of carcinomatous affections of the intestines.

CONCRETIONS IN THE STOOL

GALL-STONES, PSEUDO-GALL-STONES, BILIARY CALCULI, STONES, INTESTINAL CONCRETIONS, AND OTHER INTESTINAL CONCRETIONS

In cholelithiasis an attack of biliary colic is followed by the appearance of gall-stones from time to time. These stones may appear without any previous biliary colic. The stool should be thoroughly mixed with water and passed through a sieve. The Boas stool sieve¹ is provided with a water connection and washes the stool thoroughly. If certain, we should examine the stools during the cessation of the attack of colic.

Gall-stones are concretions which form in the intestine. They vary in size from a pinhead to that of a pigeon's egg, or even larger. They consist of cholesterol and calcium bilirubin, in varying proportions of these constituents. Besides these there are pseudo-gall-stones.

¹ A bit may be teased apart or, better, frozen and cut. The fragments may be placed in formaldehyd (R. Formaldehyd solution venale (40 per cent.)) for 24 hours; but it does no harm to leave them in it longer. The pieces are then frozen either with the formalin or in alcohol, cut, the sections are placed in 50 per cent. alcohol and cleared in cedar oil. By this method the sections are said to be the ordinary freezing process.

² Deut. med. Woch., 1900, No. 36.

in, bilifuchsin, bilihumin, and calcium carbonate. Cholesterin gives a light, calcium bilirubin a dark, color to the concretion. The color varies according to predominance of one or the other of these constituents, between white and brown or dark olive green. Sometimes they are soft enough to be readily crushed, but often, on the contrary, are rather hard. The cross-section shows distinct concentric layers of crystalline structure, sometimes of different colors. In other cases the surface may present very beautiful facet formations, tetrahedra and cubes or multiangular shapes result. Sometimes the surface is irregularly granular, a point of diagnostic importance. If facets be numerous and regularly shaped, we may be sure of the presence of multiple concretions, and, in the absence of such, of their origin in the gall-bladder. Round stones occur singly and in small numbers. Very large stones (larger than hazelnuts) hardly ever reach the large intestine *per vias naturales*, but probably always by perforation of the bile-passages into the bowel.

One must be careful not to confound other solid residues of the feces with gall-stones. *e. g.*, woody bits of plants, especially from the cores of pears. Such formations have been termed *pseudo-gall-stones*.¹ Microscopic examination of a small fragment scratched off with a knife from such a formation shows characteristic wood-cells (Fig. 212). Chemical examination (see below) would also prevent any mistake. Besides, the wood-like concretions are much harder than even the hardest gall-stones. They are called "*biliary sand or gravel*," in the majority of cases, concretions of these small pseudo-gall-stones. Perhaps the occurrence of biliary sand or gravel (see p. 518) has been responsible for the erroneous assumption of biliary sand. The existence of true biliary sand (*i. e.*, large numbers of the smallest gall-stones) in the feces has not been surely proved as yet. Naunyn considers it improbable, because his investigations show that these concretions are readily dissolved in the intestine, and because they would not be found in any such large quantities at one time, but gradually, as they were

Fig. 212.—Wood-cell from the seed of a pear (after Bizzozero).

Another kind of pseudo-gall-stones is the concretion which consists of fats and soaps that are not easily melted. They are found in the stools after the administration of large amounts of olive oil in treating cholelithiasis. Hence, the overestimation of the therapeutic value of this oil. It is difficult to understand this. These artificially produced concretions are characterized usually by their softness and soft, greasy consistence, and, if the biliary passages be not occluded, by their greenish color, due to impregnation with bile.

Even a careful and prolonged search may fail to find the concretion in certain cases of *gall-stone disease*, sometimes because the stone, which impacted in the neck of the gall-bladder and so caused the colic, has turned to the bladder itself. In other cases the stones which are impacted have become stuck in the ductus choledochus while the patency of the biliary passage has been reestablished without dislodgment of the stone. Finally, the concretion may be disintegrated in the bowel before it escapes detection. Naunyn's experimental investigations seem to prove that the latter is very often the case. He believes that ordinarily only the more solid gall-stones (for instance, those with a solid cholesterin shell) are found in the feces. Another explanation of the fact that where no gall-stone is found in the feces after the typical symptom-complex of cholelithiasis is the following: typical attacks of colic may be due to inflammation with or without gall-stone. Numerous experiments have disproved the old idea that the colic arose mechanically by the passage of the stone through narrow places of the ducts. These experiments show that an inflammation of the bile-passage and a resulting spastic peristalsis are the essential features of a gall-stone attack, and that a typical picture of such an attack may occur without the presence of a gall-stone.

¹ Compare Fürbringer, Verhandl. d. XI. Cong. f. inn. Med., 1892, p. 313.

For *chemical examination* gall-stones are first extracted with alcoholic ether to dissolve the cholesterol, recognized by allowing the solution to evaporate and the characteristic glistening cholesterol crystals separated under the microscope by their sharp, linear, rhombic cleavage. The residue is then extracted with alcohol and ether the residue is washed with very dilute potassium hydroxid. If the powder is dissolved in a yellow solution, with which Gmelin's reaction may be obtained, it is probable that some concretions contain only bilirubin. If Gmelin's reaction will be absent and only the blue color is obtained after treatment with KOH is, for the most part, solution is accompanied by effervescence.

The much rarer *pancreatic concretions* differ from the gall-stones in coloring-matter, and, chemically, in consisting of calcium carbonate, which dissolves with effervescence in hydrochloric acid.

Intestinal Stones or Fecal Concretions; Earthy Concretions with Organic Salts.—These play an important role in the causation of appendicitis. They appear very rarely, but almost exclusively of ammonium and magnesium carbonate, and are formed in the same way as urinary calculi. (See p. 517.) In most cases, which were not sufficiently explained by the presence of concretions, consisting of finely ground sand, consisting of finely ground glass, which is used in periodic attacks. Perhaps these cases have been of biliary origin. (See p. 517.)

Some concretions found in the stools consist of concretions of magnesium carbonate and phosphorus, magnesium carbonate, and combinations of bismuth subnitrate. Salol is also a well-known cause of concretions. Naunyn observed the passage of concretions of salol after ten years' use of the tincture of rhubarb. The formation of shellac concretions is well known in joiners and has been used in alcoholic solutions of shellac as drinks. In the case of "pseudo-gall-stones" consisting of fat which a cod liver oil cures.

ANIMAL PARASITES IN THE INTESTINE

PROTOZOA

Of the protozoa, there have been observed in the intestine, the ciliates (Fig. 215), sporozoa of the species *Coccidia* (Fig. 216), and species *Megastomum* (Fig. 214), *Cercomonas* (Fig. 218), and infusoria of the species *Balantidium*. Sometimes the protozoa penetrate the intestinal wall and so cause

Fig. 218.—*Cercomonas hominis*: Length, 9 to 11 μ ; width, 4 to 5 μ .

known to-day, possess no definite diagnostic significance, on the other hand (see p. 431), they have a great importance. Cohnheim and Zabel have observed that the presence of the parasite in the esophagus and stomach favors their appearance in the intestine. This suggests, under some circumstances, the ex-

¹ Arch. f. klin. Med., vol. lxx, parts 1 and 2.

² Askanazy, Wien. med. Woch., 1900.

na. The parasites of the species *Ameba* have become of more importance because they are supposed to be the cause of dysenteric-like disturbances (5). *Amebæ* are organisms with streaming, creeping (so-called ameboid) movements. They are 10 to 15 μ in diameter, and consist of a protoplasmic substance containing granules and vacuoles, which changes its shape in an irregular manner during the movements. Each ameba has a nucleus within it, which is, however, very easy to see. Propagation takes place by division; the formation of spores has not been definitely proved. Some amebæ have permanent types (permanent amebæ). These are small, round, with a sharp, often double, con-

Encysted form.

—*Megastoma entericum*: Length, 15 to 17 μ ; breadth, 9 to 11 μ (after Roos Deut. Arch. f. klin. Med., vol. li, p. 506).

and are immobile. The death of an ameba is indicated by the cessation of ameboid movements (Fig. 215), and the organism then disintegrates so rapidly that it is not easily recognized. Quincke claims that the permanent types, on the contrary, may remain visible in the stool for twenty days.¹ Pure cultures have not yet been successfully made, so that it is difficult to obtain any light on the life of the individuals found.² *Amebæ* are sometimes found in normal intestinal discharges. Large numbers are found quite regularly in tropical dysentery. *Streptococci* are also very frequently found in dysenteric stools along with the amebæ, so that in some cases are probably due to mixed infection. The amebæ penetrate the

Fig. 215.—*Amebæ* of dysentery (after Lösch).

intestinal ulcers, and are also found in the pus of dysenteric abscesses, which is of great importance for their etiologic significance in tropical dysentery. In isolated cases of the non-epidemic dysentery amebæ have been found (Quincke), which, in contrast to the amebæ of tropical dysentery, are not pathogenic for cats. Quincke recommends the following nomenclature: *Amæba intestinalis vulgaris* for the organism which is sometimes found in the stools of healthy individuals; *Amæba coli* for the organism found in dysentery. Quincke and Roos, Berlin. klin. Woch., 1893, No. 45; Janowsky, Zeit. f. klin. Med., 1897, xxxii, 5 and 6; Roos, Arch. f. klin. Med., vol. li. After staining the specimen should be washed in water until no blue color is noticeable in the wash-water, cleared with alcohol and finally embedded in Canada balsam.

Enthelmintha (Intestinal Worms)

Discovering the eggs of one of the intestinal worms is almost as important, from the diagnostic point of view, as discovering the organism itself. A low power is the best to employ at first, and then a higher one. The stools should either be liquid or mixed with water. It is often sufficient to scratch off particles of feces from the edge of the stool opening with a microscope spatula, or to obtain some from the surface by introducing the finger protected by a rubber cot. The eggs of *Ascaris vermicularis* is not infrequently discovered in this way. Larger quantities of feces may be obtained by introducing a thick glass tube into the rectum (Quinke). If the eggs cannot be demonstrated upon microscopic examination, administering some cathartic (castor oil) will often be of service, probably because the liquid intestinal contents will be more evenly mixed. (For the characteristic peculiarities of the eggs of the different species see below.)

Neither eggs nor bits of the parasite be found after the administration of an ordinary cathartic, the next procedure is to give the patient a strong anthelmintic, *e. g.*, santonin. In case of ascarides this will serve the purpose of diagnosis and treatment; but for tape-worm it is inadvisable because the drugs may do harm and should be administered only when necessary. In such a case the diagnostic dose should be moderate—about one-third of the usual therapeutic dose, *e. g.*, for *Triclistrum filicis*. If a tape-worm be present, segments will then certainly be passed. In the interest of the patient too much stress cannot be laid upon the advisability of making an accurate diagnosis (segments of worms or eggs) before undertaking the actual cure.

Hensen¹ has drawn attention to the diagnostic importance of Charcot's crystals in the stool (see Fig. 278, *e*, p. 707) for the recognition of intestinal worms. These crystals occur in the feces with every variety of helminthiasis, and often in very large amounts. They are often very numerous and require an oil-immersion lens for identification. Their relation to the presence of worms is not yet plain.

Blood Examination with reference to the almost constant occurrence of Charcot's crystals and eosinophilic leukocytosis in the various types of helminthiasis.

Nematodes (Round-worms)

***Ascaris Lumbricoides*.**—This is the only ascaris which occurs frequently in the human intestine (Fig. 218). The diagnosis of ascaris is generally very easily made, either from the eggs or from the worms themselves. The latter are 10 to 15 cm. long, white to dirty brown in color. They are almost always evacuated with the stool at one time to time, and sometimes may be vomited. The ascarides eggs are found in such great numbers with the feces that the examination of bits of feces passed at the anal orifice is usually sufficient. They differ from all other entozoa in their peculiar, irregularly wavy, albuminous shell, usually stained with feces. (See Fig. 218, *c*.) This envelop may, however, be absent. The longest diameter of

Bothriocephalus (Dibothriocephalus) L. of all human tape-worms, attaining sometimes segments are nearly square (about 5 mm.); the grooves as broad as they are long—10 to 15 mm. by 1 mm. called in this case "plerocercoid") occurs in eel-pout (*Lota vulgaris*), perch (*Perca fluviatilis*), the trout (*Trutta vulgaris*) as well as in the grass carp (1 mm. broad, 2 mm. long, with a slit-like sucker). The sexual opening in the proglottides is not at the middle of the surface. The uterus is situated at the base of a roset. The eggs have a thin shell, with a lid at the top, and can thus be easily removed. They are, moreover, larger than the eggs of the broad tapeworm. In the young ova it is not always easy to see the undeveloped or occupies only the extreme pole, in bothriocephalus we usually find longer pieces of stool. The segments do not occur so often as in the ova is of especial diagnostic importance. Anemia are due to the presence of this parasite. It is examined in every case of severe anemia whose cause is not the intestine is very rapid (about 8 cm. a day). It is found four hours after infection. Although as many

a

one patient, they usually occur singly. The following is the effect of a cure. (For Blood Findings.)

Bothriocephalus cordatus is similar to *B. latus*, but narrower (greatest width, 8 mm.) and not nearly so flattened, and broader than that of *B. latus*. The eggs are a little larger (0.075 to 0.05 mm.). They are found in Iceland, Greenland). The usual hosts are the

OCCURRENCE OF OTHER ANIMAL I

The occurrence of insects in the human bowels. These cases include the occasional, accidental infestation and specific nature of which nothing can be certain that these mites are not identical with those probably derived from tainted food (cheese, dried fish, etc.), but still quite rare, is the occurrence of the infestation of the intestine and stools (myiasis intestinalis). Schindler reports of about 100 such cases. Various species are especially mentioned being made of the following: (flower-flies), *Sarcophaga carnaria*, and *Musca domestica* (house-flies). It is assumed that the insects enter the food in the form of eggs or larvæ. In other cases they enter the bowel through the anus (especially in children) and live for a long time in the bowel because they

¹ Wien. klin. Woch., 1902

ved that the sharp hooklets arranged around the individual segments of the permit their mechanical attachment and forward motion in a direction opposite peristalsis. There are certain enigmatic cases in which the larvæ of the voided over and over again at considerable intervals, often for years at a time. This indicates either a peculiar constitution of the intestinal canal of the host, or favors the repeated fixation of the ubiquitous parasites after their introduction; a condition known as pædogenesis, which has been observed in certain dipylidæ, meaning an asexual multiplication of the larvæ. The last-named process has never, been noted in precisely the species which here enter into consideration. Regarding the clinical picture, it should be stated that in certain cases the presence of larvæ in the bowel gave rise to no special manifestations; whereas in other cases more or less severe clinical symptoms referable to the digestive organs were dependent on the presence of the parasite. In view of the frequently large numbers of the excreted larvæ (up to 1000 individuals), such a pathogenic effect is conceivable. Grave symptoms were observed especially by Schlesinger and Michaelbaum (*loc. cit.*). Sometimes the larvæ are vomited. (See p. 431.) For more detailed information and for illustrations and a full bibliography, see the index.

EXAMINATION OF THE STOOLS WITH REFERENCE TO THE UTILIZATION OF THE FOOD

THE VOLUME OF THE FECES

If the amount of food consumed a day be known, a certain amount of information may be obtained by ascertaining the volume of the feces. This can be done by weighing the feces in a measuring cylinder, and adding water until they are completely covered. If the amount of water added be subtracted from the volume of the feces plus the stool, the result gives the volume of the feces.

TEST-MEALS FOR THE EXAMINATION OF THE FECES

By means of microscopic and chemical examination much may be learned concerning the utilization of food. Strassburger and Schmidt have suggested that the examination be made under more definite conditions than with the ordinary diet. The test suggested by Schmidt has the following composition:

Morning.....	0.5 liter milk and 50 gm. toast.
Forenoon.....	0.5 liter porridge, made as follows: 40 gm. oatmeal, 10 gm. butter, 200 cc. milk, 300 cc. water, and one egg.
Day.....	125 gm. hashed meat, with 20 gm. butter, fried so that the interior is quite rare; 250 gm. potato, made by cooking 190 gm. potato with 100 cc. milk and 10 gm. butter, the whole boiled down to 250 cc.
Afternoon.....	Same as morning.
Evening.....	Same as forenoon.

This diet contains 2234 calories, 102 gm. of protein, 111 gm. of fat, and 191 gm. of carbohydrate. The diet should be given for at least three days, in order to insure that the feces really represent the diet. Under ordinary conditions this occurs after three or four days. To be sure of this, 0.5 gm. of carmin in a capsule may be given with breakfast. The first stool will then have a reddish tinge.

Against this type of test-meal it may be objected that, as in all test-meals, no account is taken of the individual peculiarities of the patient, and further its composition. For a hearty eater, it may be too little. From the standpoint of the health of a subject it is not so important to arrive at conclusions regarding what the patient can eat, as to know how he digests what he ordinarily consumes, so long as enough one obtains with such a standard diet exact and comparable results, although not of very great value for diagnostic purposes. For the practitioner the important point is not to compare different individuals regarding their capacity for eating, but to be able to obtain a diet suitable to correct his digestive disturbance. A diet which does not correspond to the usual dietary habit of the patient is of little useful information on this point. The author is also not altogether certain that much may not be done by the administration of so full a diet to a patient suffering from a disturbance of digestion.

MICROSCOPIC EXAMINATION OF THE UTILIZATION AND SPI

Incomplete utilization of the fats is a macroscopic examination of the stool. Stools of fat appear light colored, gray, peculiar, a microscopic admixture and partly of large fat-drops in the manner in which it was administered. (See also the manner in which it was administered. (See also 278, a, p. 707.) Their appearance depends on the nature of the fats, and upon whether the fats are found in the stool. Neutral unsaponified fats may appear as thick, short needles or as small droplets. In addition of osmic acid colors fat microchemically is only characteristic for fats which contain unsaturated fatty acids. They remain unstained or require the addition of an alcoholic solution of Sudan III. They differ from neutral fats in their ready solubility in alcohol. Fatty soaps, in contrast to fatty acids and

Normal stools contain a moderate number of fat-drops. Fats that are not easily melted, and are, therefore, not so common except after abundant use of fatty foods. They usually signify an insufficient utilization of fats. An abundance of fat-needles indicates an abundance of fat-needles.

The stools may be abnormally fatty in the case of a deficiency of bile when the bile is shut off from the intestine. (See also the examination of fat, such as is contained in milk, see Examination of Feces, p. 541.)

MICROSCOPIC EXAMINATION OF THE UTILIZATION OF

The microscopic appearance of starch granules. Starch-granules are characterized microchemically by the addition of Lugol's solution. Well-preserved starch granules are found in the normal feces of an adult, but they may be absent in the case of a deficiency of starch. Statements in regard to the value of starch in the diet of adults are of limited value, because after a deficiency of starch the starch-granules are evacuated undigested. Under normal conditions starch-granules which are not digested, so, too, does raw starch.

An abundance of starch-granules in the stool is usually a sequence of diarrhea or of gastric juice. Gastric juice does not seem to cause the appearance of starch in the feces, because the starches, along with the other foodstuffs, are extensively digested by the intestinal bacteria under normal conditions. The presence of starch in the intestinal contents is not responsible for the appearance of starch in the feces, as the bile contains only traces of a diastatic enzyme.

MORPHOLOGIC EXAMINATION OF THE UTILIZATION OF THE MUSCLE-FIBERS OF THE OTHER PROTEIDS OF THE FOOD (Feces.)

Muscle-fibers and Connective Tissue.—Muscle-fibers are digested microscopically by the more or less thorough digestion (see 229, aa). The more thorough the digestion, the more are the ends of the fragments rounded off. The color of the fragments is characterized by their own color and in part by the color of the connective tissue. Undigested muscle-fibers are constantly found in the stool. The amount becomes pathologically increased in the case of other disturbances of the digestive chemistry.

¹ Millon's reagent is a dilute filtered solution of Millon's reagent. (See p. 604, Note 1, for its preparation.)

of muscle fragments occurring in feces indicates a complete absence of the digestive function. On the other hand, their disappearance does not of itself lead to the conclusion that the function of the pancreas is perfect (decomposition). (Schmidt's nuclei test, p. 508.)

Connective tissue fragments of connective tissue are generally readily recognized even macroscopically by their fibrous structure; this also characterizes them microscopically, and their pronounced clarification upon the addition of acetic acid. They can be distinguished from mucous shreds by their much firmer consistence, more distinctly fibrous structure, and the disappearance of the latter structure after the addition of acetic acid, which renders mucus striated. They differ from fibrin in the absence of regular or trellis-like appearance. With an ordinary diet such connective tissue remains occur frequently in the stools in health. To discover connective tissue in the stools should be stirred with water and examined over some dark substance (plate). (See Examination of Sputum.) The connective-tissue fragments can be recognized as white fibers.

According to Kühne's¹ and A. Schmidt's investigations, raw connective tissue is dissolved by the gastric juice only, whereas cooked connective tissue is also easily dissolved by the pancreatic juice. Hence the amount of connective-tissue remains in the stools depends upon the amount ingested, upon the degree of boiling or roasting of the meat, and upon the gastric function. Starting from the same premises the author made use of in devising his desmoid test, Schmidt estimates the gastric

Scattered among these elements are microorganisms and debris (after von Jaksch).

by determining the amount of connective tissue in the stools after the ingestion of his test diet (p. 529), since experience has convinced him that the stools normally contain any connective-tissue remains after the ingestion of 125 gm. of roasted chopped meat. He claims² that the macroscopic appearance of muscle-fibers in the stools of a patient who has ingested a test-meal of 125 gm. of lightly roasted chopped meat demonstrates some severe damage to the intestinal digestion. On the other hand, the occurrence of macroscopically visible remains of connective tissue is indicative of insufficient gastric digestion, because connective tissue, unless it is cooked to pieces, is dissolved only by peptic digestion. Undigested egg-albumen and casein may be found in amorphous masses in normal stools, and more especially in stools denoting insufficiently utilized food. The granular lumps of casein are important diagnostically, because they compose the major part of a poorly digested infants' stool. A normal infant's stool is homogeneous and even. The curds of casein are, for the most part, brownish to yellow externally by the fecal coloring-matter or by altered fermentation. Inside they often remain white. Microchemically, they are characterized by an almost complete solubility in 5 per cent. HCl and KOH solution. In the latter solution they can be precipitated by acetic acid and redissolved in excess of the same. The well-known microscopic "yellow granules," which

acid of the stomach. Later investigators, who worked with anaërobic culture-media and varied culture-media, could not corroborate these results; they found that the number of varieties was much larger.

The possibility of making use of bacteriologic examinations of the intestinal contents except for the demonstration of specific pathogenic bacteria for practical purposes seems, therefore, less hopeful than Bienstock's investigations suggest.

An essential difficulty of an exact study of the intestinal flora depends upon the fact that many of the normal bacteria and of those occurring under pathologic conditions in the stools are destroyed through the physiologic action of the organisms. These are so specifically adapted to the vegetative conditions in the intestines that they cannot be cultivated in vitro. There is always a striking contrast between the enormous number of bacteria which the microscope shows and the relatively few which one can cultivate. This is a great obstacle to progress in our knowledge, and especially so because intestinal bacteriology plays a very important rôle in intestinal diseases, but also in the etiology of other infectious maladies.

The Bacterial Species Which Occur in Normal Feces

The bacterial and fungus species of normal intestinal contents have been more thoroughly studied of late. (See the comprehensive treatises of Mannaberg,¹ Schmidt and Strassburger.² These studies have proved that by far the majority of fecal bacteria belong to the colon group. Among the better known species are the *Bacillus lactis aerogenes*, the *Bacillus subtilis*, *Bacillus proteus vulgaris*, *Bacillus butyricus* (*Bacillus pasteurii*). It is worthy of note that bacteria known to be pathogenic, such as staphylococci, streptococci, and pneumococci, are frequently, perhaps constantly, found in normal feces, but they are of no diagnostic significance unless in sufficient numbers to be noticeable in dried smears. A rapid estimate of the bacterial content of the feces may be obtained by studying a particle of the stool (mixed with water if necessary) under the microscope (using the oil-immersion lens and a very closely closed diaphragm). The numbers, shape, and motility of the bacteria may be studied. For more exact microscopic examination, dried specimens are prepared in the same way as from the sputum (see pp 709 and 715), and stained with carbolfuchsin or by Gram's method (p. 715). To distinguish a group of bacteria which takes different stains it is better to stain first with Gram and then with a dilute solution of carbolfuchsin (1:10). The usual culture-media (bouillon, gelatin, and agar plates) may be employed to determine the species. Faintly acid-fermenting in agar plates has been recommended for cultivating the intestinal bacteria. Several species which do not grow in the ordinary nutrient media thrive in anaërobic media. Anaërobic cultures are occasionally necessary for fecal bacteria.

The investigations of Escherich, Moro, and Tissier on the intestinal bacteria are interesting. Escherich found the meconium of the new-born free from bacteria. The first bacteria are found four to seven hours after birth at the earliest. According to Strassburger and Schmidt, most of the bacteria in the stools of breast-fed children are Gram-positive. According to the investigations of Moro³ and Tissier there are probably two chief species. The one, aerobic, is designated by Escherich as *Bacillus acidophilus*, the other, anaërobic, by Tissier, as *Bacillus bifidus*. These species require special cultivation: the former in an acid, the latter in an air-medium. The same investigator found the bacterial flora in the stools of infants fed with cow's milk less characteristic and more diversified. The Gram-positive bacteria do not preponderate to the same degree. Hence the stools of infants fed with cow's milk constitute a transition between those of nursing infants and those of adults, in which the Gram-positive bacilli normally play quite a subordinate part, and very frequently almost no Gram-positive bacteria are found in the normal stool. Under physiologic conditions only colon bacilli and a few colonies of *Bacillus lactis aerogenes* can be cultivated from the stools of adults.

The examination of the stools, of course, furnishes information concerning the contents of the lowest portion of the gut only. The contents of the small intestine, occasionally obtained from fistulæ, are entirely different. They are not only much less rich in bacteria, but also contain different species, especially the liquefying bacteria, *Escherichia coli commune*, *Bacillus lactis aerogenes*, staphylococci, and other species which are rarely met with here as well as in the large bowel.

For the introduction to Nothnagel's Diseases of the Intestines and Peritoneum, there is also a complete bibliography.

that laboratory distilled water, when permitted to stand for some time, is the habitat of an acid-fast bacillus, easily mistaken for the tubercle bacillus. The paper and the almost universal failure of careful workers to confirm Koch's findings of tubercle bacilli in the blood also discredit his observations [Ed.]

Bacilli of Cholera, better, Cholera Vibrios (Comma Bacillus) (Fig. 231).—Demonstration of cholera bacilli is of great importance in the early diagnosis of cases of a cholera epidemic; and also in detecting the so-called "cholera carriers," i. e., individuals who, during cholera epidemics and in the neighborhood of cholera patients, harbor the cholera vibrios in their intestines, and so are capable of transmitting the disease without being sick themselves. This is of great public importance, and also essential in determining when further isolation of convalescents can be dispensed with. The bacilli are constantly present in the stools of cholera patients, and at times in very great quantities. By demonstrating their presence, the differential diagnosis between cholera nostras and Asiatica, so very difficult, may be made with certainty in an isolated case and without waiting for an epidemic. A dry specimen should be prepared from one of the fecal flakes suspended in the stool, and then stained in the ordinary way with carmalum, gentian-violet, or methylene-blue. (See Examination of Sputum.) Cholera vibrios (Fig. 231) are slightly bent rods with an average length of 1.5 and 2.4 μ . They are bent not only in one plane, but so as to resemble the thread of a needle, and are so arranged as to form varying shapes, e. g., the letter S. Actively

Fig 231.—Cholera bacilli ($\times 1000$) (after Weichselbaum).

They possess a single terminal flagellum, which can be stained with the ordinary method for staining flagella. The vibrios themselves are Gram-negative. Microscopic examination for comma bacilli is not enough to make a diagnosis very sure, because there are other comma-shaped bacilli, as, for example, Finkler and Prior, found in cholera nostras. Moreover, a negative microscopical result without any culture tests would not permit the absolute exclusion of cholera.

The vibrios grow best upon rather strongly alkaline media. Kolle obtains good results by adding 3 cc. of a 10 per cent. sodic hydrate solution to 100 cc. of a neutral to litmus. The usual plate cultures with gelatin made alkaline as above are employed for demonstrating the organisms culturally. After twenty-four to thirty-six hours numerous liquefying colonies will be found, from which gelatin stab and potato cultures are to be made. The gelatin stab cultures are characteristic in the fact that the gelatin on the surface is liquefied very rapidly in a funnel-shaped depression, whereas in the interior the liquefaction occurs only as a slender zone along the line of inoculation. On potato the comma bacilli grow rather well at 20° C., as a thin, gray-green coating. The use of agar plates is very important for the rapid diagnosis of cholera, because they can be kept at incubator temperature. The agar must be strongly alkaline. Petri dishes make the best plates. After inoculation the covers should be removed and the plates turned upside down and dried for about five minutes in a drying chamber at 60° C. A very small amount of the suspected material is, as slowly and evenly as possible, rubbed upon the surface of the plate with a Drigalski spatula (a glass rod bent at a right angle).

According to Kolle, isolated colonies which turn brown in 24 hours at 36° C. (see below).

The comma bacilli may sometimes be found in the Comprehensive data relative to the comma bacilli are to be found in Pfeiffer's extensive monograph, 1892, No. 36.

A government publication by Koch, 1891, describes the bacteriologic methods of diagnosis and gives information for studying the suspected material.

If the comma bacilli be cultivated in 10 cc. of water, and 0.5 gm. of NaCl to 100 cc. of water, and concentrated sulphuric acid be then allowed to be added, a line of junction will occur at the line of junction of the two liquids, the lower being retained in the culture (nitrosoindol). This is a characteristic of cholera but the name is not quite correct, because other bacteria. If the culture be not a pure culture, it is of diagnostic importance. Cholera vibrios do not occur, provided that true cholera bacilli are present. The peculiar motility of the comma bacilli is shown in aqueous peptone cultures.

Biologic methods (Pfeiffer's test and agglutination of pure cholera cultures transferred from agar slants and isolated best by means of a needle.) are necessary especially at the beginning of an epidemic of other vibrios resembling those of cholera.

Pfeiffer's (bacteriolytic) test is accomplished by the injection of a lethal amount of young guinea-pigs with an injection of a definite amount of culture. If they be true cholera bacilli, they will be killed. Pfeiffer¹ claims that other vibrios, which resemble cholera bacilli, do not show this property.

The Agglutination Test for Cholera.—If a small amount of cholera be added to a liquid culture of cholera, the bacteria will agglutinate in clumps, very much as do bacteria in serum. (See Widal's Serum Diagnosis, p. 100.) Different methods of examination in the diagnosis of cholera upon circumstances. The morphologic and biologic recognition of suspicious cases during an epidemic of vibrio colonies in agar cultures made direct from the patient. On the other hand, great caution is necessary in the culture method with peptone water (see above). Cholera is retained in great numbers, and this is not the case with other vibrios. The use of the biologic tests with pure cultures and they must certainly be employed to determine where cholera has not previously existed.

Typhoid Bacilli.—Typhoid bacilli from typhoid patients from the second or third week of the disease (and plate cultures) are, of course, necessary for diagnosis. Typhoid bacilli do not possess any typical characters, but the differentiation is, however, so complicated and tedious that it is of importance in the diagnosis of typhoid fever. To prevent the occurrence of epidemics, or to prevent individuals who, after their fever, or even with a relapse, may be bacilli and so endanger others. The reader is referred especially to Pfäundler's work² on typhoid bacilli; and to Kühne's work upon the typhoid bacilli. A brief account of some of the most important features.

Most methods consist in the preparation of pure cultures.

¹ Zeit. f. Hyg., 1895, vol. xix, p. 75.

³ Kolle and Wassermann, Handbuch der Bakteriologie, vol. i, p. 100.

media of which are added certain substances which are known to have a different influence upon the growth of typhoid and other fecal bacteria, especially the colon bacillus. In this way a degree of selection is favored, or at least there is produced a distinctive macroscopic appearance to the individual colonies sufficient to allow of their recognition and to point the way to other more accurate methods of examination.

The author selects for description the method of Drigalski and Conradi.¹ The so-called Drigalski's agar is prepared as follows:²

(a) About 3 pounds of chopped beef are left to stand in 2 quarts of water for twelve to twenty-four hours. The meat is then pressed and the fluid obtained is boiled and filtered. 20 gm. of Witte's peptone, 20 gm. nutrose, and 10 gm. salt are added, after which it is boiled again, filtered, and 60 gm. of agar added. This mixture is then boiled in streaming steam for three hours and made faintly alkaline to litmus, filtered, and boiled again.

(b) Litmus lactose solution. The litmus solution, prepared according to Kubel-Tiemann, may be obtained from C. A. F. Kahlbaum in Berlin. Ten cc. litmus solution is boiled for ten minutes, 30 gm. chemically pure milk-sugar added and the mixture boiled for fifteen minutes.

(c) *a* and *b* are mixed while still hot, well shaken, and the mixture made alkaline again by the addition of 4 cc. of a sterile 10 per cent. solution of anhydrous soda. Finally, 20 cc. of a solution of 0.1 crystal violet (Mark O. Höchstler-Farwerke) in 100 cc. of sterile water is added. This should be freshly prepared each time. The mixture is poured into 200 cc. flasks and can be kept for a long time.

Plate cultures can be prepared from this medium by selecting a small amount of the feces to be examined and rubbing it over the surface of the hardened agar by means of a Drigalski spatula. Four plates can be inoculated from one streaking of the spatula, and so successive dilutions obtained for isolation of the germs. Instead of Petri dishes, larger covered dishes, 15 to 20 cm. in diameter, and 1 to 2 cm. deep, are recommended. The agar is poured into the plates to a depth of not less than 2 mm. Before inoculation the surface of the medium must be freed from water of condensation by setting the uncovered plates upside down in the drying oven. For cultivation, the plates are kept at 37° C. with the cover down, so as to avoid any water of condensation. Upon this medium there is a blue area about the typhoid colonies, while the colon bacilli, on account of the production of acid, are surrounded by a red zone. The existence of colonies which do not alter the blue color of the medium is not, of course, sufficient for the demonstration of typhoid bacilli, but merely points to their selection for more careful investigation by the methods to be described below, and excludes the greater proportion of the colonies of the colon group.

Another culture-medium which is recommended for a bacteriologic diagnosis of typhoid is E. Roth's³ and Ficker and Hofmann's⁴ caffein bouillon. This favors the growth of the typhoid and inhibits that of the colon bacillus. It is prepared as follows:⁵

Sufficient soda solution is added to stock bouillon to neutralize the latter, using tested phenolphthalein as an indicator. The bouillon is then sterilized and 80 to 100 per cent. of its volume of a 1 per cent. caffein solution is added. In preparing the latter, pure commercial caffein is dissolved in boiling distilled water. The bouillon is inoculated with a tiny amount of the feces to be examined, and kept at 37° C. This exalts the typhoid bacilli, and the exalted bouillon culture is then prepared and examined on plates according to Drigalski's and Conradi's methods.

For isolating typhoid bacilli from the stools Loeffler's selective malachite green has been much employed recently. Loeffler's later modifications of the method are to be found in the *Deutsche medicinische Wochenschrift*, 1908, No. 39, p. 158.

If some of the colonies obtained according to one of the above methods suggest those of the typhoid bacillus, an orientation agglutination test is made. A platinum needle is inoculated with a tiny particle selected from one of the suggestive colonies, and mixed upon a glass slide with a drop of typhoid immune serum of a titre homologous strain. The mixture is then covered with a cover-glass one edge

by the convenient Gruber-Widal agglutination reaction of typhoid. (See later, Blood-examination, p. 857.) To be sure, the utility of this procedure for recognizing typhoid bacilli has of late been questioned, although the value of the serum reaction as a diagnostic measure is now hardly ever disputed.

Dysentery Bacillus.—While tropic dysentery seems to be an amebic disease (see p. 519), F. Shiga¹ in Japan, Kruse² in Germany, and Flexner³ in the Philippines, have described a peculiar bacillus as the exciting cause of non-tropic epidemic dysentery. These bacilli are found as plump rods in the purulent and mucoid portions of the stool, sometimes in almost pure cultures, and often within pus-cells. Shiga's and Kruse's bacillus coincide in the essential feature, but Flexner's organism, though closely related, presents some distinctive features. The clinical significance of this distinction is thus far of no more importance than the differentiation between the typhoid and paratyphoid bacilli. [This whole subject has been carefully reviewed by Flexner in Aibutt's System of Medicine, vol. ii, part ii, p. 495 et seq. Herter⁴ agrees with the author and similarly objects to the term "paradysentery bacillus," because it appears to have been shown that the lesions caused by these bacteria are identical with those caused by the Shiga bacilli. Further, he says: "The Shiga bacilli are the cause of the severe epidemics of Japan and of Germany, but in the latter country bear the name of Kruse. The Flexner bacilli are apparently the cause of dysentery in young children much more frequently than the Shiga bacilli. . . . The Shiga and Flexner organisms, however, taken together, do not quite cover the entire range of bacillary dysentery; for, as Park and His have shown, there are pathogenic bacteria intermediate in type between the two. . . . Shiga⁵ has lately adopted the classification of His, which recognizes four groups based on fermentative characters, and has added to this a fifth, intermediate between the acid bacilli and the non-acid bacilli."—ED.] To avoid any prejudice, it is usual to speak of a Shiga-Kruse type and of a Flexner type of dysentery bacillus. They grow readily upon artificial culture-media, forming firm, non-liquefying, leaf-like colonies upon gelatin plates within twenty-four to forty-eight hours, which closely resemble typhoid colonies. According to Kruse, they are found in such large numbers in the fresh stools of dysentery that in plate cultures their colonies greatly exceed those of the colon bacilli. Like typhoid bacilli, they grow upon glucose agar either superficially or in the depths, without producing gas. Upon potato there is a yellowish growth along the line of inoculation, surrounded by a clear area. In bouillon they produce a uniform turbidity, with a sediment but without a scum, and without the formation of indol. (See p. 538.) They grow upon milk without curdling it. They behave like typhoid bacilli in litmus whey, and do not change neutral red agar. Their cultures upon agar develop a very characteristic sperm-like odor. They may be differentiated from typhoid bacilli, which they resemble so closely, by their plumpness and also by their lack of motility and the absence of cilia. They do not stain by Gram's method. They sometimes exhibit distinct polar granules. Kruse believes that the relation of these micro-organisms to dysentery is shown by the fact that they are agglutinated by the blood-serum of a dysenteric patient in a dilution of 1:50, and sometimes by a dilution of even 1:1000. Under certain conditions the agglutinative power of the serum of a dysenteric convalescent may last for a year. In reference to the diagnostic value of the agglutinative reaction, the reader is referred to Lentz's⁶ article, as well as that of Kolle and Hetsch.⁷ There is little danger of confusing typhoid and dysentery bacilli from any given case, because the clinical pictures of the disease they excite are so different. The significance of the bacteriologic examination of the stools in dysentery may best be expressed by saying that, in case not all the bacteriologic distinctions can be made, the demonstration of typhoid-like bacilli in the stools of a case showing the symptom-complex of dysentery argues for a bacillary dysentery.

Streptococci.—A number of serious diseases have recently been attributed⁸ to an invasion of the digestive tract by streptococci. Their course is like that of

typhoid, cholera, or, finally, of an act (peritonitis, endocarditis, nephritis, etc.) from a microscopic examination of the extraordinary quantities of streptococci stained with carbolfuchsin or by Gram. The urine may sometimes contain abundances. The disease is usually fatal, except in those cases in which the patient recovers. (See pictures of streptococci, Fig. 284.)

Pneumococci.—According to the literature (see Fig. 281, p. 716) is a frequent cause of death at times merely by a febrile reaction, at times by a septicæmia. The diagnosis is made by finding large diplococci in the stools.

Anthrax Bacilli.—Anthrax can be detected by the presence of anthrax bacilli in the loose, frequently

[For further information upon the diagnosis of anthrax, the reader is urged to consult Herter, *The Common Diseases of Man and the Intoxications Arising from Them*, p. 100.]

CHARACTERISTIC NATURE OF

Stools of Typhoid Fever.—Typhoid stools are yellow, of the consistence of pea-soup, with a thick, granular sediment and a sulphureous odor. The odor is generally very strong and offensive. The reaction is usually strongly alkaline. In fact, microscopic crystals of triple phosphates (see Fig. 257) are often seen. Simple microscopic examination is usually characteristic. Typhoid bacilli can be detected by the use of and time-consuming culture methods. A slight tinge not infrequently precedes the disease. Pus in the stools is to be carefully watched for. Pus microscopically is contained only in the stools of the early stages. The diarrheal stools of typhoid fever occur not infrequently, not only in the early stages but also during the duration of the disease.

Stools of Asiatic Cholera and Cholera nostras.—In Asiatic cholera and cholera nostras the stools are watery, colorless or grayish, like water in which starch has been dissolved. The absence of any brown color is characteristic. The stools no longer emit a fecal odor. The reaction is alkaline or neutral. In the mucous films of the stools the epithelium is arranged in layers, more or less thick, and sometimes drops of fat. The stools are watery. (Cholera stools contain only a small amount of sodium chlorid, and but very little of the other salts.) The stools are profuse, unlike those of dysentery, and the general condition improves, they are not fatal. In well known cases of cholera do occur.

The stools of *cholera nostras* are not watery. True cholera bacilli are absent, and the disease, they are more or less stained. The stools of *cholera nostras* contain very varied numbers of bacteria, streptococci, and others, see pp. 535 and 536.

Stools of Dysentery and Carcinoma of the Colon.—The stools present the character of rectal diarrhea, but voided so much the oftener. Soor stools are watery, slimy, or serosanguinolent (meat-juice stools), or solid, reddish or white fragments, (caruncles of older writers) and partly quaternary necrotic mucosa. The stools are not fatal but in grave cases (gangrenous flux) they are. (See pp. 519 and 539 in regard to the presence of amebæ in tropical dysentery and carcinoma of the colon.)

The stools of carcinoma of the rectum sometimes very closely resemble those of dysentery.

Stools in Diseases of the Pancreas.—Considering the prominent part played by the pancreas in the digestion of fats, it is easily understood that in some of the diseases of this organ which lead to its destruction or to the occlusion of its ducts, so-called "*fat-stools*" are observed. The latter are characterized macroscopically, microscopically, and chemically by their abnormal content of fat (steatorrhea). We must, however, be rather cautious in making use of this symptom for diagnosis, because, on the one hand, the stools may show an abnormal amount of fat in any case of marked icterus, and, on the other hand, cases of almost total destruction of the pancreas have been observed when the stools at the time showed no abnormal amount of fat. This is because emulsified fat, even without any pancreatic juice, can be very readily absorbed, as shown on p. 530, while evidently the fat not in emulsion is taken care of by the vicarious action of the bile. Hence fatty stools are diagnostic of pancreatic disorders only where there is no jaundice, and hence also the absence of fatty stools does not exclude destructive pancreatic disturbance. In making a diagnosis of pancreatic disturbance from the appearance of the stools we must also remember that, if the pancreatic juice be absent, chemical examination shows only insignificant quantities of soaps in the fatty stools (p. 544), the stools show but slight signs of putrefaction, and the urine contains only a slight amount of indican. (See p. 579.) Upon a mixed diet the stools contain a considerable amount of isolated muscle-fibers; and if raw meat has been eaten, these fibers show, according to A. Schmidt, preserved nuclei, provided the pancreatic function is entirely wanting. Larger pieces of muscle tissue are found only if the gastric digestion also is disturbed, so that the connective tissue is not dissolved. In pancreatic disease, where there is no flow of pancreatic juice into the intestines, well-hardened glutoid capsules (see p. 506 et seq.) are found undissolved in the intestinal contents, providing the gastric motility be normal. The iodoform-glutoid reaction is therefore absent. See also the demonstration of trypsin in the feces (p. 542 et seq.). Under certain circumstances a negative test for this ferment must be considered in the diagnosis of pancreatic disease.

CHEMICAL EXAMINATION OF THE FECES

REACTION OF THE STOOLS

Under normal conditions the reaction of the feces may be neutral, faintly acid, or faintly alkaline. Gamgee, as well as Nothnagel, considers a faintly alkaline reaction the most frequent. At any rate, under normal digestive and nutritional conditions, the reaction is not far from neutral. The reaction on the surface of formed feces often differs from that in the interior. The reaction may also change upon prolonged standing; it should, therefore, be tried on fresh stools. An admixture of urine will very soon produce an alkaline reaction. Pathologically, the reaction may become either strongly acid or strongly alkaline, according to the kind of decomposition processes which are occurring in the intestinal canal. Typhoid and cholera stools are usually alkaline. The stools of a patient upon a milk or a starch diet are usually, but not always, acid in reaction. The absence of gastric juice (achylia) curiously enough does not affect the reaction of the feces. Deficiency in bile produces acid stools.

PIGMENTS OF THE FECES

The color of the feces of normal adults is never due to unchanged bile-pigment (bilirubin), because the latter is transformed into urobilin in the intestine, and partly reabsorbed and used over again in the organism (probably to help form bile and to produce urinary pigment). Therefore the presence of bilirubin in the feces always indicates some abnormal function of the intestine—either some disturbance in absorption or in the chemical processes, or else some increased peristalsis. Bile-pigment often appears in diarrheal stools. It can then sometimes be recognized by its intense yellowish or greenish shade. Chemically, it can be very easily demonstrated by Gmelin's test (p. 575), *i. e.*, by dropping a little fuming nitric acid directly

one must eliminate the action of the leukocytic ferments. This may be done by using the serum of cold-blooded animals, *e. g.*, turtles, which contains an antibody to the leukocytic ferment, but which does not inhibit trypsin. Without this control a positive result is of no value in indicating the efficiency of the pancreatic digestion, and thus the method loses in its usefulness.

In a similar way Müller¹ uses starch plates to demonstrate pancreatic ferments in the feces, but it has been shown that the diastatic action still persists, although to much less degree, when the duct is completely occluded.

MUCIN IN THE FECES

Stools normally contain considerable mucin, which is increased in catarrhal conditions of the intestines. Sometimes the appearance and consistence of the feces (see p. 511 et seq.) are enough to show this. According to Hoppe-Seyler, mucin can be demonstrated chemically by mixing the feces with water, adding an equal volume of lime-water in which mucin is soluble, and then adding dilute acetic acid to the filtrate. Cloudiness indicates mucin.

Strassburger and Schmidt point out that this test is not sufficient, for nuclealbumin gives a similar reaction, and it is necessary to show that the precipitate is free from phosphorus. The substance ought to reduce an alkaline copper solution after it has been digested for some time with 7.5 per cent. hydrochloric acid. Practically the differentiation has no significance.

PROTEIN AND PEPTONE OR PROTEOSES IN THE FECES

The detection of these substances by means of the biuret reaction must be performed with special caution, because the urobilin which is contained in the feces also reacts to this test (extracting urobilin with alcohol; see p. 569). Normal feces are free from any soluble proteins, peptones, and proteoses, but they can be demonstrated under pathologic conditions, especially diarrhea.

Schlossman² dilutes the feces with water, filters, precipitates the nucleoproteins and mucin by the addition of 30 per cent. acetic acid, filters again, and tests for proteins by the heat coagulation test, using sodium chlorid, the potassium ferrocyanid test, or the nitric acid test. (See Section on Urine, p. 563.)

CARBOHYDRATES IN THE FECES

Unaltered starch is best demonstrated microscopically. (See p. 530 and Fig. 201, *i-n*, p. 428.)

To show the presence of sugar, feces are boiled with water, then filtered, and the filtrate tested by Trommer's test or by the phenylhydrazin test (pp. 587 and 591). See also the Schmidt-Strassburger fermentation test (p. 532 et seq.).

QUANTITATIVE AND QUALITATIVE TESTS FOR FATS, FATTY ACIDS, AND SOAPS IN THE FECES

Even a microscopic examination of the stool will enable one to form some estimate of the content of fat (p. 530).

If it be desired to estimate the total amount of fatty substances (fats, fatty acids, and soaps), the Liebermann-Szekely method may be used (Pflüger's Arch., vol. lxii, 360, 1898). The feces are boiled with 30 per cent. potassium hydroxid until all the fats are saponified. The fatty acids are set free with sulphuric acid, dissolved in petroleum ether and alcohol, and titrated with alcoholic potassium hydroxid, using phenolphthalein as an indicator.

To estimate the amount of neutral fat, fatty acids, and soap separately³ a weighed amount of the stool is dried at 100° C., then mixed with several times the quantity of sand, which has been treated for several days previously with water, alcohol, and HCl, and then again with water. The feces-sand mixture is now extracted with ether, by means of Soxhlet's apparatus, until no more fat can be removed. This

the clarifying of this ether extract. A few cubic centimeters are poured off, and 10 drops of a freshly prepared tincture of guaiac and 20 to 30 drops of old, so-called ozonized oil of turpentine are added. The green coating which forms on guaiac resin on exposure to air must be removed by scraping before the alcoholic solution is prepared. If blood be present, the mixture will turn violet blue; if not, it turns red brown, with often a slightly greenish tinge. The reaction is more marked if we add some water and then extract the blue pigment with chloroform. In healthy individuals the feces never react positively to this test unless the diet contain an

excess of meat (see below). Weber found the test sensitive enough to demonstrate blood-pigment in the daily movement of a healthy individual after the ingestion of only 3 cm. of blood. Sources of error inherent in the method are mentioned below.

According to Boas,¹ the guaiac test for blood does not always yield decisive results in the examination of the feces, since the blue color is often veiled by the brown shades and rendered indistinct. For this reason Boas recommends a control test with aloin, as suggested by Klunge, Schär, and Rossel. According to

¹ Deut. med. Woch., 1903, No. 47.

Rossel,¹ the test is performed as follows: 5 cc. of ether, in order to remove the fat, which the test by the formation of emulsions. A few cc. of acetic acid are added to the feces, and ether in a test-tube. The acid ethereal extract is employed for the investigation. A solution of as much aloin as can be placed upon the point of 60 to 70 per cent. alcohol. To the acetic acid 30 drops of a resinous oil of turpentine, and of aloin; if the stool contain blood, the result, and upon standing for a time assumes a cherry color. An aloin solution remains yellow for at least on a slightly reddish tinge. According to Boas, the reaction is accelerated or made more distinct by the addition of this modification, agitation of the mixture results in the formation of floccules which settle in the bottom of the tube under certain conditions Boas regards the aloin test as the most reliable. According to Brandberg, the oil of turpentine is replaced by hydrogen dioxid.

Adler's Benzidin Test for Blood.—O. and Schlesinger and Holst² recommend benzidin. Cohnheim³ recommends the following procedure: Benzidin (Merck) is dissolved in 2 to 3 cc. of acetic acid and poured into 2 cc. of commercial hydrogen peroxide. A small amount of the feces are boiled in water, cooled, and a few drops of the extract are added to the solution. In the presence of blood, a blue color is produced. According to Citron, the test is better performed with acid ether. A small amount of acetic acid and ether. To the extract a small amount of hydrogen dioxid. In the presence of blood, a blue color is produced.

Errors in the Detection of Blood.—The above tests are extremely sensitive, but must be accepted with caution. They all depend on the presence of a catalyzing agent, such as old oil of turpentine or hydrogen dioxid, which is called a superoxydase action. Other substances, such as the hemoglobin derivatives of the muscle tissue, food, certain plant and animal ferments, and these are excluded by employing the ether extract. That certain salts of iron and bismuth are also capable of giving the results. In order to avoid this it is necessary that before the test has been made, the patient has not taken any of the mentioned drugs. Plant and animal ferments are not soluble in the ethereal extract. Meat acts in exactly the same way as the blood. It is necessary, in performing the test, to exclude all other substances before the test is made, so that at least two weeks before the test has been withdrawn.

The Spectroscopic Detection of the Derivatives of Hemoglobin.—The hand spectroscope (direct vision, after Brownian type). The material to be tested must be white, and the light by transmitted sunlight or in daylight. The test-tube is moved by moving the inner tube, so that Fraunhofer's C line is pointed toward a white surface or toward a white card, and to make an examination with an ordinary cap B (see Fig. 232), made of brass and blackened over the prism end of the spectroscope, and the test-tube, with the substance to be examined, is placed in the light is admitted through B.

The normal pigments of the feces, even in small amounts, frequently mask the characteristic spectrum of

¹ Arch. f. klin. Med., 1903, vol. lxxvi, p. 54.

² O. and R. Adler, Zeit. f. physiol. Chem. Schumm and C. Westphal, *ibid.*, 1906, vol. xlv and Holst, Münch. med. Woch., 1907, No. 10.

³ Die Krankheiten der Verdauungsorgane

diffuse absorption of light; hence a mere watery dilution of the feces is not to be recommended in doubtful cases. The following method is more desirable: Several cubic centimeters of the stool to be examined are mixed with water and acidulated with several drops of sulphuric acid until the Congo-red reaction is marked. (See p. 450.) The mixture is then filtered, and the filtrate extracted with ether. If the ether does not separate properly, the extraction may be hastened by adding a few drops of alcohol. If the feces contain blood, the ether turns reddish brown and shows spectroscopically the characteristic bands of acid hematin in the red. (See Fig. 233.)

Of course, the hemoglobin of muscle-fiber gives the same reaction and the same spectrum as the hemoglobin of blood, so that we must be careful to exclude any mistake by seeing that the patient does not ingest any large amount of raw or half-cooked meat.

SIGNIFICANCE OF THE DETECTION OF BLOOD IN THE FECES

The significance of the presence of extremely small amounts of blood in the feces is very great, in the early diagnosis of cancer of the stomach or of the intestines, ulcers of the stomach, tuberculosis of the intestines, typhoid fever, and other conditions of the digestive tract associated with hemorrhage. Boas¹ has shown that in cancer of the stomach constant occult hemorrhages occur. This is of importance not only as a diagnostic sign, but as indicating the cause of the cachexia and anemia of these patients. It is very noteworthy, however, that in pernicious anemia one also has the constant presence of occult amounts of blood in the stools. This complicates the differential diagnosis between this condition and that of carcinoma of the stomach. [Most of the recent literature upon this subject has been reviewed by White,² in a very comprehensive paper to which the reader is referred. He compared the value of the Weber guaiac test with "hydrogen dioxid (see above, Brandberg's modification) and the Schlesinger and Holst benzidin test; 95 per cent. of his positive results were in cases of cancer or ulcer of the esophagus, stomach, or bowel. One hundred and six examinations of the feces with the benzidin test in 88 cases, including healthy persons on a meat-free diet, neuroses of the esophagus, functional diseases of the stomach and bowel, chronic gastric and intestinal catarrh, gallstones, syphilis, and cyst of the liver, gave only negative results; 48 examinations of the feces in 15 cases of acute or chronic ulcer of the stomach or bowel or hepatic cirrhosis gave intermittent positive and negative results; 20 examinations of feces in 8 cases of cancer of the esophagus, stomach, or bowel gave only positive results. . . .

"One hundred and eight examinations of feces in the 88 meat-free and non-ulcerative cases gave identical negative results with the two tests; 20 examinations of feces in the 9 cancer cases gave identical positive results; 30 examinations of feces in the 9 cases comprising acute gastric and duodenal ulcer, ulcerative colitis, and cirrhosis gave identical positive or negative results. Of the 46 positive tests with benzidin in 144 examinations of the feces of sick persons, all but 3 were positive with guaiac. Of the 87 positive tests with benzidin in sick persons (including results of 144 examinations of feces, and 131 examinations of gastric contents), all but 11 were positive also with guaiac.

"These 11 positive results with benzidin in sick persons (where the guaiac test was negative) are distributed as follows: 3 were examinations of feces and 2 of gastric contents in chronic ulcer, where the somewhat greater delicacy of the benzidin test was distinctly useful in diagnosis; 6 were examinations of gastric contents in cases where examination of the feces by both tests was negative. The fact that a few more positive results were obtained in the gastric contents in this class of cases with benzidin than with guaiac is not an important matter, as we place little value on a positive result in gastric contents after the use of a stomach-tube when the feces are negative. The objection that the benzidin test is too delicate for clinical work is removed by the use of the Schlesinger and Holst modification as far as my experience goes in the constant use of the test for almost two years.

"The chief advantages of the benzidin over the guaiac test are the greater value of a negative result in ruling out all hemorrhage, the much greater ease and rapidity of its performance, and the greater clearness of the color reaction in the feces.

"Those who wish at first to control their results with benzidin by means of the guaiac test will find a great amount of time saved by applying the benzidin test first; it takes only two minutes to perform, and a negative result renders any further test unnecessary."—Ed.]

URINARY I

AMOUNT

The daily volume of urine excretion under average conditions between 1500 and 2000 cc. Intake of fluid will considerably increase and intake of fluids or food will correspondingly decrease. It will vary in inverse ratio to the temperature; it diminishes and cold weather increases it. In fever, diarrhea, and vomiting all decrease. In children or abnormally small individuals it is correspondingly less. The normal average has been determined from the following formula: x represents the weight of a healthy adult to be 75 kilos (165 pounds).

$$x : 1500 = 2$$

where x represents the daily amount of urine excreted of the individual in kilos. Children excrete on account of the preponderance of water in their portionally a larger amount of urine than adults.

According to Martin and Ruge,² 67 per cent. of the urine of the first day of life, but generally 60 per cent. of the remaining 33 per cent. do not voided until the third day. The daily amount of urine excreted is 100 cc. and 200 cc. Ranke, Bischoff, and others have determined the third to the fifth year as about 700 cc.

As a rule, less urine is voided at night than during the day.

According to Quinke,³ this condition is more pronounced during the night than during the day in arteriosclerosis, in cachexia, and usually in heart disease. The amount voided at night may be contrasted with the normal proportion of the watery, but the solid, constituents are the same. This phenomenon is the result of a nocturnal retention (heart and kidneys). It may, however, be a delay in the water excretion may be delayed abnormally slowly, and not until night, fluid ingested during the day.

THE COLLECTION

[Much work has been done by various methods in which the urine has been collected. It has proved to be worthless. This is the case with the collection of the urine where a twenty-four-hour collection is made. It may be said without reserve that

¹ [In this country the average quantity of urine excreted falls considerably below this. The figure is 1500 cc.]

² Vierordt, *Daten und Tabellen*, 188.

³ *Arch. f. exp. Path. u. Pharm.*, vol.

no value for examination except for certain qualitative tests. These are: specific gravity, reaction, presence of albumin, indican, glucose, urobilin, acetone, and for microscopic examination. These may properly be performed with a small specimen of urine. All quantitative tests made with a sample of urine of which the twenty-four-hour quantity is not accurately known are useless. Unfortunately, they are also worse than useless, for they may lead the clinician to use the results so obtained for diagnosis which are based on entirely wrong premises. It must be pointed out that the fact that a urine contains 2 per cent. of urea, 4 per cent. of glucose, or 0.1 per cent. of albumin is of no importance except in so far as it shows that the urine contains urea, glucose, or albumin. What is of importance, however, is to know that a patient is excreting 30 gm. of urea, or 100 gm. of glucose, or 1.0 gm. of albumin in the twenty-four hours. This information is only to be obtained when a twenty-four-hour specimen of urine has been collected.

To obtain a definite twenty-four-hour specimen of urine, an hour should be fixed at which to start. It is best to start at 8.00 A. M. The patient should be instructed to urinate at this hour, and all urine passed at this time should be discarded. During the subsequent twenty-four hours all urine voided should be collected,¹ and at 8.00 A. M. the following morning the patient should be instructed to empty the bladder, and this should be added to what has already been collected. In this way the whole amount of the preceding day is obtained. The urine is most conveniently collected in wide-mouthed two-quart preserve jars fitted with a screw or patent top. A few cubic centimeters of chloroform should be placed in the jar before collecting the urine, and after each addition the contents of the bottle should be well shaken. It is well to keep the bottle in a cool place. No time should be lost in submitting the urine to examination after the collection is complete.

So much misdirected treatment has been made on the basis of statements based on the percentages of substances contained in the urine—statements which are completely inadequate—that it has seemed advisable to point out clearly the necessity of obtaining a complete twenty-four-hour specimen.

In view of what has been said regarding the influence of under-nutrition on the composition of the urine, it is also of importance to know the composition of the food taken at the time the urine is collected. Information of this kind is of great significance when, either from a pathologic condition, or as the result of diet, the patient is losing weight. If the food be analyzed, particularly for its nitrogen content, one is able to ascertain whether a loss of weight is due to the consumption of fat and carbohydrate, or whether the muscle and other protein-containing tissues participate in the loss. In every instance treatment must be directed to guard against a loss of protein material to the body. This can only be done intelligently when the amounts of nitrogen in both food and excreta are determined, and the one balanced against the other. A concrete example of this will make the case clearer.

Any attempts to reduce weight in obesity by means of diet must be made with the idea in mind of preventing a loss of muscle tissue. The loss desired must be at the expense of the carbohydrate, and particularly

¹ The patient must be especially warned against loss of urine during defecation. Before going to stool the bladder should be completely emptied of urine.

ily induced by disturbances of metabolism, *e. g.*, the polyuria in diabetes mellitus, which, in the author's experience, has reached as high as 18½ quarts.

FREQUENCY OF URINATION

Although varying decidedly in different individuals, the frequency of urination corresponds in general to the amount of urine excreted. It is also influenced, however, by any inflammatory affection of the urinary tract or by any disturbance of innervation of the bladder. The increased frequency of urination (usually of less amounts than normal) from inflammatory conditions of the urinary tract depends upon a stimulation of the bladder reflexes (pollakiuria). It is generally accompanied by the subjective sensation of urgency (bladder tenesmus). Although observed chiefly in affections of the bladder, and especially of its neck or of the urethra, this frequent voiding of urine may depend also upon kidney disease, resulting either from a pathologic reflex emanating from the kidney, or from the irritation of an abnormal urine upon the mucous membrane of the bladder. Diseases of the spinal cord which either increase the irritability of the bladder or weaken the sphincter are also responsible for an increased frequency of urination. An abnormally infrequent urination depends upon some mechanical or nervous obstacle to the emptying of the bladder. (See later, *Examination of the Nervous System, Innervation of the Bladder.*)

SPECIFIC GRAVITY OF THE URINE

For the sake of simplicity the specific gravity of the urine is ordinarily expressed in four figures, taking the specific gravity of distilled water as 1000 instead of 1. Special aërometers called urinometers are employed for this purpose. Their scale is marked from 1000 to 1050. To insure a correct reading the subdivisions should be sufficiently wide apart. Many urinometers are not very accurately constructed, so that it is always well to compare a new instrument with a reliable one, or at least to ascertain whether it reads 1000 in distilled water at the ordinary room temperature, 15° C. (60° F.). Although a very large urinometer is more accurate, a smaller instrument requires less urine, which sometimes is a distinct advantage.

In the determination of the specific gravity the urine is poured into a tall glass cylinder [a urinometer and an appropriate glass cylinder are generally obtained together.—Ed.], the urinometer is immersed in the urine, and then, with the eye at the level of the surface of the urine, the subdivision which corresponds to the upper part of the curve of the meniscus is read off. For the sake of accuracy, the cylinder should be sufficiently large to allow the urinometer free motion. The bulb of the urinometer should not be allowed to stick against the side of the vessel, all bubbles or froth should be removed from the surface of the urine by means of filter-paper, and the urine should be at the ordinary room temperature. If the urine be colder than 15° C., one-third of the urinometer unit should be subtracted for every degree of Centigrade below the ordinary temperature; if warmer, the proportionate amount should be added. Ordinarily, such corrections are of slight significance, but they assume decided importance in diabetes insipidus and in other diseases accompanied by pronounced polyuria and a diminished specific gravity of the urine (chronic nephritis), because in such conditions the specific gravity of the urine is but slightly above that of water. In diabetes insipidus, for example, the influence of the temperature of the urine, if these corrections be not made, may mask the uniformity of the specific gravity characteristic of this affection. Since the specific gravity

of individual specimens of urine varies so is imperative that the specific gravity of a twenty-four-hour secretion be obtained if it be drawn from the results concerning the circulatory or secretory organs.

If the specimen be too small to work is a simple matter to dilute it with distillation, to estimate the specific gravity of the late the specific gravity of the urine, at least.

The specific gravity of a twenty-four-hour specimen normally from 1015 to 1020. Copious specimens bring it as low as 1002; excessive perspiration as high as 1040. The variations in the specific gravity are due to the gain or in the loss of water from the skin or from the marked differences which occur in single twenty-four-hour specimen.

Pathologically, the specific gravity is determined by the parenchyma of the kidney, by the velocity of excretion, and by abnormalities of metabolism. The amount of urine affects the specific gravity in a certain manner, so that the specific gravity usually varies with the amount of urine. Both under physiological and pathological conditions, therefore, a scanty urine is more concentrated. In acute nephritis the urine is concentrated and of a high specific gravity. In chronic nephritis, due to a true contraction of the kidney, the urine is of a low specific gravity. Diabetes mellitus is an exception to the above rule, since the excretion of sugar produces an excessive amount of urine; this is a diagnosis is often possible on this ground alone. There are also exceptions to the above rule, such as in uremia and concomitant diminution in the excretion of water. (See also cases present a low specific gravity with a high specific gravity.) Again, in some cachectic conditions, even in advanced metabolism and the lessened ingestion of food produce a fall in volume of urine and, at the same time, a fall in specific gravity.

The urine in diabetes insipidus is excreted in large volume. The urine has the extremely low specific gravity. The volume of urine is correspondingly high—usually more than 30,000 cc. have been excreted. If the water be restricted, the specific gravity of the urine rises. (See also Olqvist, E. Meyer, and F. Seiler have shown, which has been used for therapeutic purposes in various disturbances, which seem allied to uremia, to be dependent on a hyperosmotic condition of the blood.) A full protein diet does not have a decided influence on the specific gravity of the urine in healthy individuals. In the urine of patients suffering from diabetes insipidus, if water has been restricted, a retention of water, increased thirst, and only after the intake of water does the patient eliminate the excess of water. Associated with polyuria the kidney adapts itself to the condition.

of solids to be excreted than does the kidney in diabetes insipidus. But occasionally one sees a condition in the former disease which is very close to that of the latter.

The specific gravity is a fairly accurate indication of the amount of solids excreted in the urine. The solids excreted in 1 liter of urine can be approximately represented in grams by multiplying the last two figures of the specific gravity by 2.2337.¹ A urine of high specific gravity is called *concentrated*. The urea is mainly responsible for the specific gravity. For this reason alone, apart from the diminished secretion of water, a fever urine is always concentrated.

In reference to the value of the determination of the specific gravity of the urine as a substitute for the cryoscopic urinary examination, see p. 668.

TRANSPARENCY OF THE URINE

Freshly voided normal urine is absolutely clear and transparent, but after it has been standing for some time, an indistinct cloud of so-called mucin, "the nubecula," appears. (See p. 571.) Various other insoluble substances may cloud pathologic specimens of urine. (See the section on the Sediment and Turbidity of the Urine, p. 669 et seq.)

COLOR OF THE URINE

NORMAL URINARY PIGMENT

The color of the urine varies normally within different shades of yellow, the depth of color increasing in direct proportion to the specific gravity. The abundant urine of a drinker or of a person with contracted kidneys may be as pale as water, as contrasted with the scanty urine of acute nephritis, of passive congestion, or of fever, which is almost always dark. In diabetes mellitus, despite the high specific gravity, the urine is remarkably pale. This is of similar diagnostic importance as the great increase in amount. The urine in anemic individuals is always paler than normal, except in pernicious anemia. There the urine is quite dark, because this disease is associated with a rapid destruction of the red corpuscles, and, as is well known, the urinary pigments are derived from the hemoglobin.

The only method of designating the color of the urine is to compare it with certain fixed shades on a chart. In Neubauer and Vogel's book,² unfortunately, only a few different shades are represented. Radde's³ scale can be used for other purposes as well, and is more highly recommended. Naturally, to obtain uniformity of results, a certain uniform thickness of the urine must be observed in each case, and the specimen must be held against a white background. For the quantitative determination of the normal urinary pigment (urochrome) see p. 612.

¹ Vierordt, Daten und Tabellen zum Gebrauch für Mediciner, 1888.

² Anleitung zur qualitativen und quantitativen Analyse des Harnes, older editions. In the more recent editions, edited by Huppert and Thomas, this plate is no longer included.

³ Otto Radde, Stenochromatische Anstalt, Hamburg, 1877.

that, if the urine show any peculiar or extraordinary color not otherwise explainable, we should consider the possibility of attributing it to the administration of some drug.

Carbolic acid, coal-tar products, hydroquinone, resorcinol, pyrocatechin, naphthalene, salol, the arbutin derived from the leaves of *Uva ursi*, and many other aromatic substances, when administered internally, and sometimes even when employed externally, produce a dark, olive-green to black urine. The dark color frequently becomes apparent only after considerable exposure to the air or after the urine becomes alkaline. It depends upon the formation of colored compounds by the oxidation of the excreted drugs. Hydroquinone and pyrocatechin are especially prone to result from such oxidations, and they cause the dark color of urines containing phenol, salol, and arbutin.

The appearance of this color in the urine should occasion no alarm unless one of these drugs is being used externally; as, for instance, in the old Lister antiseptic employment of carbolic acid. Then the drug is evidently being absorbed in considerable and uncontrollable amount, although not intended to be absorbed at all. As a product of excretion simply, the dark color is of no particular significance. The dread of it is largely due to the frequency with which it was met after the use of the carbolic spray of Lister's method. Often quite moderate doses of salol (2 gm., 30 gr., a day) will be accompanied by the excretion of a black urine without any ill effects, while doses large enough to cause toxic symptoms may cause no discoloration. These variations depend to a considerable extent upon the degree of acidity of the urine, as well as upon the length of time it is exposed to the air.

The administration of *chrysarobin, rhubarb, senna, or cascara* may produce a yellow or reddish-brown urine, which will become distinctly red if the reaction is alkaline. (This is due to the presence of chrysophanic acid; see p. 612.) *Santonin* is apt to produce a saffron-yellow or greenish color, which changes to red if the urine be rendered alkaline. (See Test for *Santonin*, p. 612.) The pigment of *madder*, of *beets*, and of *huckleberries* may, under certain conditions, be excreted in the urine (Gorup-Besanez).

ODOR OF THE URINE

Normal urine possesses a peculiar faint odor which is not particularly unpleasant. The disagreeable, so-called urinous odor depends upon bacterial decomposition taking place either in the urinary tract or after the voiding of the urine. It is often called ammoniacal, since ammonia can usually be demonstrated in such a specimen. There are, however, other odorous substances concerned besides ammonia, as one can appreciate by the sense of smell, *e. g.*, aromatic decomposition products (phenol). Decomposing albuminous urine presents an odor so characteristic as to justify a definite diagnosis of the presence of protein.

Decomposition in the urinary tract, or the absorption of hydrogen sulphid from putrefactive areas in the body, will sometimes produce an odor of sulphuretted hydrogen (hydrothionuria).

Various odorous substances, if introduced into the body, appear directly as such in the urine, *e. g.*, the odorous substances of valerian, leek, castor, crocus (saffron), *asafetida*, meat, bouillon, and coffee. Other substances, from characteristic odorous compounds in the body about which little is understood, but which are excreted in urine, *e. g.*, balsams, especially the balsam of copaiba, cubebs, saffron, and the oil of turpentine. Even small doses of the last impart a very distinct odor of violets. The peculiar odor of the urine after eating asparagus is due to methylmercaptan (Nencki).

turned blue without being immersed, or if, when a glass rod in dilute hydrochloric acid is held over the surface of the urine, fumes of ammonium chlorid are produced, or if we note a strong ammoniacal odor, the reaction is caused by a volatile alkali, probably ammonia. Moistened red litmus-paper suspended for a sufficiently long time—quarter to one-half hour, over a normal acid urine will become showing that a certain amount of ammonia, even without any bacterial fermentation, is given off by a freshly voided acid urine; but the color will disappear when the paper is dried. It is characteristic of urines which owe their alkalinity to fixed alkalis that only on the immersion of red litmus-paper in the urine will the paper become blue, and that this color is permanent even upon the application

whenever the reaction of the urine is alkaline from free ammonia, it is to assume that the condition is the result of the decomposition of urea or ammoniacal fermentation. To decide whether this takes place within or outside the urinary tract, it is necessary to test the urine directly after it has been voided.¹

The alkaline fermentation of the urine brought about by the action of micro-organisms is characterized by the change of urea, $\text{CO} < \begin{smallmatrix} \text{NH}_2 \\ \text{NH}_2 \end{smallmatrix}$, to ammonium carbamate, $\text{NH}_4\text{COONH}_2$, and ammonium carbonate, CO_3 , with the taking on of one or two molecules of water, as they may be. These two substances, being unstable, easily break down and give off ammonia. The alkaline reaction due to fixed alkalis is caused by decomposition of the urine, but by other conditions as mentioned.

The urine of dogs has been rendered alkaline (without the aid of bacteria) by administering an excessive amount of milk of lime, ammonium carbamate being excreted.

The normal acidity of the urine may be pathologically increased by increased decomposition of the body proteins, especially in fever. The use of the acid in this case is the same as in the ingestion of food containing protein.

It is not yet definitely determined whether patients with the uric-acid diathesis excrete an abnormally acid urine. (See p. 541 for the Quantitative Estimation of the Reaction of the Urine; Titrimetry; Alkalimetry.)

SEPARATION OF THE URINES OF THE TWO KIDNEYS

Modern renal surgery frequently demands the separate examination of the urine from each kidney. This requirement is most exactly met by ureteral catheterization by means of the cystoscope, for the details of which the reader is referred to the text-books of cystoscopy.

This method requires special technical training, and may be replaced to a certain extent by the use of the so-called urinary separators, which have recently been devised. All these instruments depend upon a similar principle: the bladder is emptied, a sagittal septum is introduced into the viscus, and the separate urines are withdrawn by catheters appropriately attached to the sagittal septum. One of the favorite instruments of this type is that of Luys (Fig. 234), which is described as follows:

When it is not possible to examine the urine perfectly fresh, the addition of one-third its volume of chloroform water (1 : 200), or of a few pieces of coarsely powdered camphor or thymol crystals, will preserve the specimen. (Berap. Monats., 1903, No. 1.)

" It consists of two metallic grooves wh about the caliber of No. 22 (French), and ha eral metallic grooves embrace a third flat pie side of which possesses two eyes at one extre other. The middle piece is inclosed in a cc screw, so that it fills the concavity of the closed, the urine in the bladder is drawn, th screw, and, since the bladder is divided sag kidney may be obtained separately. Hand; to attach separate vessels to receive the uri strument may be employed in the female wit male is not attended with great difficulty o male subjects with enlarged prostates a spac catheter, which is not drained upon the int mixed urine may consequently interfere wi

This moves the tip *a* in the direction of the arrow *A* and the watch-spring tends down and stretches the membrane into the position shown in the cut *d b*). The spring and membrane are retained in place by the tiny screw *k*. In this instrument no especial practice is required for the separation of the

author has found but one objection to the instrument. The beak *a b* is considerably longer at the moment of introduction than later, when the membrane is stretched as in the cut. Consequently, it occurred to the author that the instrument be introduced as far as possible into the small shrunk bladder of a patient with urogenital tuberculosis it would not reach into the bladder as far as the outer part of it would remain within the urethra and so be very apt to lacerate the membrane as the membrane was stretched. To obviate this disadvantage the author has modified the instrument by altering the mechanism for stretching the membrane. The beak *a b* is made immovable, and the spring is bowed and forced out of the shaft into position *a c e d b* by pushing *i* in the direction of the arrow *B*. This motion is made possible by a hinge fastening the spring to the end of the sound at *a*, and a hinge at *b*, fastening it to a sliding metal rod inside the shaft, a similar principle as that of the diverticulum sound. (See Fig. 331, p. 882.) With the index-ring *h* and the thumb pushing *i* in the direction of the arrow *B*, the spring is forced forward and downward, stretching the membrane into its proper position in

Fig. 235.

der. By tightening the screw *k* this position can be maintained. Fig. 235 shows the position of the instrument in the bladder. The instrument works equally well for Lambotte's and the author's instrument.

The author has convinced himself, through experiments on cadavers, that the results of the Lambotte model which he has followed in his own instrument are perfect separation both in males and females. The size of the separating membrane seems ridiculously small when compared with that of the Luys separator. However, quite large enough, and the pronounced curve of the Luys model which makes its introduction difficult is superfluous, provided the patient is placed so that the fundus forms the deepest portion of the bladder (the dorsal elevated gynecocystitis), as the orifices of the ureter are only about 3 cm. from the internal orifice of the urethra. The two catheters must be introduced far enough into the bladder to reach the deepest point of concavity of the membrane, as shown in the cut. This can be determined before introduction and appropriate marks made at *f* and *g*. Before introducing the sound, they must, of course, be withdrawn from the shaft.

Before inserting the instrument the bladder should be thoroughly washed as in cystoscopy, with a 4 per cent. solution of boric acid, and about 50 to 100 cc. of this solution should be left in the bladder. After the introduction of the sound, the solution flows out, filling the catheters, which then act as siphons, and the urine from the trigonum trickles drop by drop into the centrifuging tubes. When the examiner becomes expert he may verify the position of the membrane by

between these two forms, it is necessary to examine the urinary sediment under the microscope and to consider carefully the entire picture.

Actual albuminuria is either dependent on the fact that the renal epithelium and probably principally the glomerular epithelium, is permeable to the proteins (serum-albumin and serum-globulin) which circulate with the blood, or that lacunæ are formed between individual epithelial cells, so that the tissue lymph produced in the vessel-walls is not held back by a continuous epithelial layer. The vessels themselves may be responsible, because physiologically they permit the transudation of albuminous liquid in the formation of lymph. The abnormal permeability must, therefore, exist in the epithelial layers. The question of a non-pathogenic albuminuria in the sense of the excretion of an abnormal protein circulating in the blood seems doubtful. The only argument for this assumption is the functional albuminuria following the ingestion of large quantities of protein food. This is not altogether convincing, for one may assign this to an irritative condition of the kidney following too great demands upon its excretory power in eliminating urea. This idea has a more reasonable basis from the finding that after the excessive ingestion of uncooked egg-albumen, the protein excreted in the urine gives the reaction for egg-albumen itself. (See, p. 562.) Whether the passage of the protein through the epithelium is always pathologic, or, in other words, whether a so-called physiologic albuminuria can actually exist, has created considerable discussion, and some misunderstanding of terms has complicated the question. Albuminuria is usually considered the most important symptom of the diffuse kidney disorders called Bright's disease. Hence the term "physiologic" has been applied to cases of transitory albuminuria which are associated with no other symptoms, and whose subsequent development proves the absence of any real nephritis or other disturbance. Examples of this form are the albuminuria observed in apparently healthy individuals, and the so-called "cyclic albuminuria," which occurs at certain hours of the day (generally after rising), especially in the morning. As a matter of fact, the term "physiologic" means merely that this type of albuminuria is not at all serious, but it is hardly an appropriate term. Just because a biologic phenomenon is harmless, it is not necessarily physiologic. It seems to the author that we are quite misled in designating as physiologic a catarrhal process which causes no discomfort to an individual, as we are in assuming such an excretion of albumin to be physiologic. It is not physiologic, but rather a result of some slight affection of the renal epithelium which causes a transient albuminuria in otherwise healthy people, unassociated with any appreciable anatomic renal change.¹ This conception is of considerable importance from a practical standpoint, because the kidney of an individual with physiologic albuminuria would naturally be regarded as more sensitive or even predisposed to actual disease, and so suggest to the careful physician appropriate prophylaxis. Perhaps its relation to actual nephritis as the alimentary glycosuria bears to actual diabetes mellitus.

According to recent researches, the minute traces of protein found quite commonly in the urine of healthy people are neither albumin nor globulin, but nucleoproteins, which has certain reactions in common with the former. (See p. 571 et

Regarding this conception of normal albuminuria "logic" has so often been misapplied, one must not detect by the ordinary clinical tests, but ones, but which are not associated with any obvious of a nephritis. These belong most distinctly to a question is simply whether they are associated with a disturbance. The presence of morphologic elements can differentiate, for in many purely functional cases. The main diagnostic point is the ascertaining of a distinct functional change in the condition of the kidney.

Of these changes, the most important is that which occurs to severe muscular effort. This phenomenon is that a degree of effort reacts differently with different degrees of effort, such as the appearance of albumin at the onset of muscular pains. Prolonged cold exposure causes albuminuria. This is probably associated with a disturbance of blood. Mental strain may cause the appearance of albumin. A characteristic of these functional disturbances is the fact that they are on the condition provoking them.

Another group of cases is that distinguished as albuminuria minima. In this class fall the albuminurias of the first ten days, and disappear without leaving any trace known. The urine found in the bladder of still-born children. Little has shown that about 50 per cent. of cases disappear. During labor the percentage is greater, and decreases after delivery.

One of the most important groups of albuminurias is the "essential." These are undoubtedly pathological. The appearance of albumin in the urine. Two of the most important are the orthostatic albuminuria of puberty and cyclic or orthostatic albuminuria. The orthostatic albuminuria described by von Leube occurs from the fourth day of life. At this time it tends to disappear. Cyclic or orthostatic albuminuria is due to the influence of position on the appearance of albumin. The urine passed during the night is free, while the vertigo of the day it reappears in the urine. Most of these cases are transient albuminurias. But some persist beyond childhood.

In most of these cases there is a decrease in the function of the kidneys, and the urine is concentrated. Some writers, like Armstrong, found cyclic albuminuria in not less than 10 per cent. of children. These were mostly weak individual children. Most of these disappeared about the age of five. All writers are not in harmony regarding the cause. According to Senator, many of these cases are due to a disturbance of the circulation, while Krehl and Broadbent oppose this view. In some cases due to functional weakness incident to imperfect development, only hyaline casts are found. Regarding the cause, some are inclined to agree with Hooker and Erlanger that it is due to a disturbance in the circulation. These cases are of its appearance the difference between the maximum and minimum is low. Others have been able to show not only albumin but maximum arterial pressure.

Phosphatic albuminurias are also found, in which, in addition to phosphaturia, one finds traces of albumin in the urine.

Nutritive albuminurias are those following the ingestion of raw egg albumen. This has only been found in healthy subjects after the ingestion of cooked egg-albumen. In nephritis uncooked egg-albumen causes a large amount of albumin in the urine. This corresponds to the escape of uncooked albumin into the circulation of an individual with the injury of the parenchyma of the kidney by the action of the raw egg.

There are also cases of albuminuria minima, in which there is a trace or the appearance of albumin in the urine without any enlargement of the heart or other clinical symptoms. In some of these cases, with the postmortem findings, less than in interstitial nephritis. Some of the cases of albuminuria minima occurrence of interstitial change is probable, but in many cases it is favorable. Many cases do not go on to the typical stage of nephritis. One can only differentiate these cases after long observation.

these cases are merely an accentuated physiologic or normal albumin. This is in harmony with the idea that the boundary between pathologic and physiologic conditions is not by any means a sharp one.

Most pathologic forms of albuminuria must certainly depend upon affection of the renal epithelium, which is most pronounced in acute and circulatory disturbances of the kidneys (nephritis) and amyloid disease of the kidneys. But the renal epithelium also may be damaged sufficiently to permit the transudation of albumin in: *general anemia, cachexia, venous congestion, transitory renal obstruction, temporary occlusion of a ureter, prolonged retention of the urine in the bladder or of the spinal cord, the circulatory disturbances attending attacks of epilepsy, temporary compression of the thorax, prolonged cold baths.* To the same category the so-called febrile albuminuria observed in various fevers belongs.

In *infective albuminuria* varies decidedly with the type of the disease. In *acute nephritis* a large amount of albumin, sometimes 2 per cent. or even though generally not more than 1 per cent.), is excreted; in *chronic nephritis* the amount varies. The more the disease approaches the stage of a true contracted kidney, despite the severity of the disease, the smaller is the amount of albumin excreted; and in an extremely severe case it may even disappear temporarily.

The same variability and temporary disappearance may characterize *albuminuria in chronic disease.*

The amount of protein in *passive congestion* is, in most cases, not so great. There are, however, exceptions, in which the amount is large. In these cases the amount of protein corresponds closely to the amount in the volume of the urine resulting from the congestion; in *nephritis*, on the contrary, the degree of albuminuria does not respond in any well-defined way to the quantity of urine. A small amount of albumin and a relatively large volume of urine are never combined in passive congestion; but such a combination is common in *nephritis*, although ordinarily only in very serious stages of disease.

Severe albuminuria rarely occurs except in the severe infectious diseases where the quantity of albumin may become so considerable that it is very difficult, perhaps impossible, to make a differential diagnosis between such albuminuria and actual nephritis.

SECTION ON PROTEINS AND RELATED SUBSTANCES IN THE URINE

Recent opinions regarding the nature of the proteins and their changes have altered so materially that the reader is recommended to consult the annexed table to comprehend the differences and mutual relationships of such of these substances as may occur in the urine. (Facing this page.)

Table of the Ordinary Coagulable Proteins of the Urine (Serum-albumin; Serum-globulin)

(The albumin test in the usual sense of the word)

Test for Albumin.—This test depends upon the principle that weakly acid or neutral solutions of albumin will be coagulated at a certain boiling-point. The coagulation temperature of the albumin occurs in the urine, and which is principally serum-albumin, lies between

ated," if the precipitate, produced by heating

mining the presence of coagulable protein. (See below in re-its advantages.) But we must remember that not only nucleo- and albumose, but also resinous acids, may be precipitated by ng the urine too strongly. (See below for the Nitric Acid Test e to the Differentiation Between Resins and Proteins.)

Tests for Albumin in the Cold.—A large variety of chemical s are capable of precipitating albumin even at a low tempera- Requiring no alcohol lamp, these tests are of distinct advantage or practitioner. The best known are:

Nitric Acid Test (Heller's Test).—One-half inch of concentrated acid is placed in a test-tube, and filtered urine is allowed to flow ne sides of the tube and stratify itself upon the acid. Albumin, nt, causes a precipitate at the line of junction of acid and urine, ms a ring or zone of cloudiness. If, however, there is only a all amount of albumin present, this precipitate may not separate er the lapse of several minutes.

er certain conditions, *e. g.*, a very concentrated urine, the uric urates may be precipitated by this test; but if the zone is quite nt, it will probably be due to albumin. To be absolutely sure the n should be gently heated (not boiled), when the ring, if due to or uric acid, will promptly disappear. Or, before testing, the n can be diluted with two or three times its volume of water, in ase nitric acid will precipitate only albumin. Moreover, the d ring is usually broader, less sharply defined along its upper and often plainly situated in the urine itself above the line of n of the two fluids.

r the internal administration of some of the balsams the nitric t sometimes brings down a precipitate of resinous acids, which confused with that of albumin. Such a precipitate, however, to some extent cleared up by heat. Or, if the nitric acid and re mixed and the liquid then sucked up from the precipitate pipet, the precipitate, if composed of resinous acids, will dis- an excess of alcohol. According to Tappeiner, it is sufficient two volumes of alcohol to the mixture of urine and nitric acid first separating the precipitate.¹ Alexander has objected that proteins precipitable by nitric acid will, under certain conditions, lved in alcohol as well as in resinous acids. He recommends the of the precipitate by the addition of ether, although a great of the latter will be necessary to prevent the formation of an n. A precipitate soluble in ether is due only to resinous acids. t test also permits a differentiation, for the resinous acids are not able by heat unless the urine has been very strongly acidulated etic acid. Alexander performs a control test by adding to the urine one-third its volume of nitric acid; any cloudiness must e due to albumin, since the resinous acids could not be precipi-

l the considerable excess of nitric acid. sinous acids is that the addition of a few ludes a cloudiness of the urine. (See p. Sandalwood Oil.)

min are also precipitated by the nitric solved by an excess of acidity, and the

Under certain conditions nitric acid precipitates concentrated urine, the urea, as urea nitrate. To avoid the error mentioned above, Hammarsten suggests a gravity of 1005 or lower. Heller's test then precipitates albumin, and albumoses, because, unless the uric acid, urea, the bile acids, nor the resinous acids can then be excluded if the precipitate persists after

Test with Acetic Acid and Potassium F strongly acidified with acetic acid, and a cyanid (1 : 10) is then added drop by drop. Albumin will cause the appearance of a precipitate. This reaction is one of the most trustworthy. Nevertheless, the albumoses and nucleo-albumins (the former, however, only when present in

Tanret's Test.—The reagent is prepared by dissolving 3.32 gm. of potassium iodid in as little as possible of water and 20 cc. of acetic acid. The reagent is added until a precipitate is produced. The reaction is due to the fact that it reacts not only with albumin, but with albumoses. The test is too delicate for the detection of pathologic amounts.

Spiegler's Test—The reagent is made by dissolving 2 gm. of mercuric chlorid, 4 gm. of tartaric acid, 20 gm. of glycerine in 100 cc. of water. A modification of the reagent is prepared as follows: 20 gm. of succinic acid, 10 gm. of sodium chlorid, 100 cc. of water. The reagent is probably the most delicate test for albumin. It is filtered and made acid with acetic acid in order to precipitate those substances which are also precipitated by the reagent. The urine is then filtered. If albumin be present, a ring is formed at the point of contact. The reagent detects albumin in a concentration of 1 part in 1000. In pathologic albuminurias the test is too delicate.

Metaphosphoric Acid Test.—If a small part of the reagent is dropped into albuminous urine, the protein will be precipitated. It has little value, because it applies only to fairly large amounts of albumin. The same precautions as before must be taken to exclude urates, uric acid, and resinous acids. The only advantage is that the metaphosphoric acid can be readily transferred from one bottle to another. It must be kept sealed to prevent the absorption of water. Ordinary phosphoric acid, which does not precipitate albumin, is of no value.

Picric Acid Test.—Picric acid, either in the form of a solution or as a solid, can be used like metaphosphoric acid. It precipitates albumin, resinous acids, and sometimes uric acid.

Since with these cold tests so many precautions are necessary, the practitioner will select the ordinary tests (see seq.) as being the most reliable and the simplest.

Appendix.—*To Remove Protein from the Urine.*—Many of the following qualitative and quantitative tests for protein are best performed on a protein-free solution of urine. The best method is to effect an insoluble combination of the protein with a reagent. Hofmeister adds 10 cc. of a saturated solution of sodium carbonate to 100 cc. of urine, and into this mixture stirs a solution of 10 gm. of sodium phosphate. The color becomes blood red. Such a mixture, when neutralized with sodium or potassium hydroxid, is very faintly acid, and then boiled, cooled, and filtered, is free from protein and iron. (Test with potassium ferri-cyanid of no value for a urine containing sugar, because it is precipitated.)

It is usually sufficient to boil an acid urine in order to remove the protein. If the urine is not acid, it should be slightly acidulated with dilute acetic acid. After boiling, a sort of cloudiness rather than in flocculi, it is acid, while still boiling, until large flocks form. If the urine does not produce coarse flocks, filtering will not completely remove the protein.

reaction be too faint, or if too much acetic acid be added, the protein may be lost from separating in large flocks. Schorer, one of the author's assistants, found that a solution of azolithmin gives a good indication for the optimum acidity of the urine. Enough of the indicator is added to color the urine. When too much acetic acid has been added, the violet tinge changes to red. If too much acid has been added, the excess may be removed by the cautious addition of a solution of sodium carbonate. If, during heating, the red color changes to violet, a little more acid must be added to bring the reaction back to the proper color. If the amount of protein be large, it is a good plan to first dilute the urine with water before attempting to make a separation. The only way to be certain that protein has been completely removed is to be sure that the addition of acetic acid and potassium ferrocyanid to the filtrate does not produce any cloudiness. If turbidity still persist, it is due to the addition of too much or too little acid, and the test should be performed again, varying the acidity slightly.

Detection of Globulin

Globulin always seems to accompany serum-albumin in urine, and is never absent without it. Regarding the diagnostic significance of the globulin content of the urine see p. 616. According to more recent investigations, there are three groups of globulin—euglobulin, pseudoglobulin, and fibrinoglobulin or fibrinogen; the last is spoken of on p. 616. The globulins are insoluble in water, and are held in solution by phosphates contained in the urine. To demonstrate globulin we add ammonium carbonate to make the urine neutral or faintly alkaline. This is done in order to precipitate the phosphates, which, in the subsequent treatment with ammonium sulphate, would produce a turbidity. Then the filtrate is collected upon a filter, and then washed with a half-saturated ammonium sulphate solution. After the resulting precipitate has settled well (one part of filtrate to one part of reagent), it is collected upon a filter, and then washed with a half-saturated ammonium sulphate solution until the filtrate is protein-free. The filtrate contains the globulin and fibrinogen, and under certain conditions, albumoses as well. The albumin has not yet been precipitated, and this requires complete saturation with the reagent. (See Table on p. 563.) The precipitate is next dissolved in a little water and the solution heated over a water-bath. This will coagulate the globulin, fibrinogen, and albumose. This precipitate is filtered, washed with water, and then digested and dissolved in a 1 per cent. solution of sodium chlorid over a water-bath. If necessary, the resulting solution can be filtered again, and then carefully neutralized with acetic acid. If any fibrinogen or fibrinogen was originally present, an albuminate will be precipitated which will not be dissolved by the addition of a solution of sodium chlorid. If the deposit consists of albumose, acetic acid gives no precipitate whatever or the precipitate is dissolved in a solution of sodium chlorid. Solutions of fibrinogen differ from those containing globulins in that the latter are not coagulated by the action of fibrin ferment (fresh blood-serum). This difference, however, is of no practical value in urinary examinations, as will be observed from subsequent observations upon the demonstration of fibrinogen in urine.

When large quantities of globulins are present, the urine, when diluted with distilled water, produces a turbidity. Likewise a drop of acetic acid produces a turbidity in urines containing much globulin if the urine be diluted with water to a specific gravity of 1006. Other substances are at the same time precipitated by acetic acid. (See p. 563.)

URINARY EXAMINA

Detection of Fibrin

in belongs to the globulins, and (above). The test for it is practical: fibrinogen will coagulate spontaneously in the presence of a ferment. Now when fibrinogen is always indicated with a *considerable* addition then resembles an ordinary coagulation; it occurs very exceptionally in the urine, so far as we know now, this has been observed in *very rare cases of nephritis*.

Detection of Fibrin

forms in the urine when the latter contains a form of small clots, which are recognized by their shredded structure, and by their physical peculiarities and their behavior will suffice for its recognition.

DETECTION OF ALBUMIN

(Albumosuria—Propeptonuria)

is *albumosuria*, *propeptonuria*, and *peptonuria* synonymous and all three included under the term *albumosuria*, because the term *peptonuria* and *albumosuria* had not been used, "*true peptone*," which has since been used by Kühne, has not been absolutely defined. (Table facing p. 563.) Another term should be included under the name of *true peptone* from the albumoses. In a single reaction, the precipitate with sulphate and the non-precipitate with sulphate does not permit of a certain of the albumoses are not *albumoses* have been found in the urine with albumin during the puerperal period, in phosphorus-poisoning, in ulcerative albumosuria, in most febrile diseases, particularly the suppurative, in pneumonia during resolution, in albumosuria the albumoses are absorbed from the intestine, and constructed into albumins. In the case of autolytic processes occurring

ence of the *albumoses* in the urine does not contain albumin. It then appears questionable

or were formed from the albumin by the chemical processes and for its removal.

presence of albumoses alone in the urine is of only limited value. But when it is very pronounced, and when there are reasons for albumosuria, it may lead to the recognition of *deep-purpuration*. This symptom must, therefore, be considered in the *of perityphlitis*, in the differential diagnosis between *tuberculousulent meningitis*, in the diagnosis of *abscess of the brain*, and of *of the pleura*, etc.

Salkowski's¹ Test for Brücke's Peptone or Albumoses.—This is a modification of Hofmeister's early method. Fifty cubic centimeters of urine free from protein are required. If the specimen contains nucleo-albumin, the may be precipitated with a little neutral lead acetate. A thick flocculent appears (with which, by means of filtration, the nucleo-albumin is removed). The filtrate is then placed in a beaker with 5 cc. of HCl, precipitated with phosphotungstic acid, and then heated over a wire gauze. In a few moments the precipitate collects in a resinous mass at the bottom of the glass. The supernatant is then decanted as completely as possible, and the resinous mass is washed with distilled water, which, if done carefully, may be accomplished with scarcely any loss. We now add to the precipitate about 8 cc. of water and 0.5 cc. of sodium hydroxid (of about 1.16 specific gravity). The precipitate now crumbles and easily when the beaker is gently shaken. The resulting solution, usually of a yellow color, is heated again over the wire gauze. It usually becomes turbid and grayish yellow; sometimes it turns yellow but remains clear. If the reaction occurs slowly, it may be hastened somewhat by the addition of a few drops of sodium hydroxid. When it is completed, the liquid is poured into a test-tube, and the biuret reaction² tried. For this purpose a dilute (1 to 2 per cent) solution of copper sulphate is added drop by drop with shaking. If peptone is present, the liquid will turn a decided red, and this color will be intensified if the solution is now filtered. The whole process does not occupy more than five minutes. The great advantage of the method lies in the fact that, owing to the small amount of urine required, nucleo-albumin is less liable to affect the reaction." The addition of a few drops of barium chlorid solution has seemed to the author to be advantageous when the solution upon which the biuret reaction is to be tried is already colored. After filtering off the resulting precipitate, the solution is decolorized.

Salkowski has discovered a source of error in his own method which decidedly detracts from its practicability.³ He found that the albumose reaction might be affected if the urine contained much urobilin, for with the biuret test urobilin gives a color very much like that obtained with the albumoses. To make the value of the biuret test absolute, Salkowski therefore considers that the solution to be shown to furnish no spectroscopic evidence of urobilin (p. 584). If the urine contains much urobilin besides albumoses, we should first extract with alcohol after acidifying, in order to remove the urobilin as completely as possible. By this plan, however, some loss of albumose can hardly be prevented. The addition of barium chlorid, as suggested above, will sometimes, but not always, free the solution from urobilin.

Salkowski⁴ modified Salkowski's test in order to eliminate the urobilin. He added to the phosphotungstic acid precipitate by centrifugalization instead of by filtration, then washes repeatedly with alcohol, which takes up the urobilin, and centrifugalizes again until it becomes absolutely colorless. The washed precipitate is then suspended in water and dissolved in sodium hydroxid, and finally

Archiv. f. d. med. Wiss., 1894, xxxii, 113, and *Practicum der physiol. Chemie*, Leipzig, 1900.

The *biuret reaction* is a color reaction common to all proteins in solution. It is, especially marked with albumoses and peptones. It is performed as follows: After an excess of sodium or potassium hydroxid has been added to the solution, a very dilute copper sulphate solution is added. It will produce a color, the shade varying according to the kind of protein present; with albumoses it is a blue violet; with peptones and albumoses it is a red violet.

lin. klin. Woch., 1897, No. 17, p. 353.

ibid., 1899, Nos. 35 and 36.

the biuret test is performed. If no cent is washed on filter-paper with alcohol.

Detection of Albumoses Accordi is first filtered, and any nucleo-albumin dilute acetic acid and removed by filtration are made—the heat test, ferrocyaning coagulable protein need not be examined. (See p. 568). If this is absent, into six times the quantity of absolute alcohol to twenty-four hours. The solution is then in a slight amount of warm water. After for precipitable nucleo-albumin with a reaction is performed. The presence of urobilin does not, as a rule, give rise to any difficulty is accomplished, the urobilin remains in the supernatant and is washed with absolute alcohol, and so on.

Detection of the Bence-Jones Sub-stance, **Kahler's Disease** (Multiple Myeloma). The Bence-Jones substance is a peculiar substance. It is characterized by certain properties of the book to classify it with the primary excretions of Magnus-Levy² and Lindemann¹ in the group of albumoses, and be placed in the Bence-Jones substance was at first found only in the urine of patients suffering from multiple myeloma (disease). Askanazy has, however, shown that for this condition, as he has also found in other cases, however, it occurred in wide variety of cases, soon ending fatally. The amount of the substance in the urine is very considerable, varying from a few drops to several ounces. The secretion ceases for a time. The substance is found in the hydropic fluid of patients suffering from multiple myeloma, but was found in the pleural fluid of a patient, due to the partial precipitation of the substance, is independent of the diet.

Detection of the Bence-Jones Substance contains the substance is characterized by its solubility in acid with acetic acid, and if it contains urobilin when heated to 50°, and at 60° C. deposits a precipitate which adheres to the sides of the vessel. By further heating, the precipitate dissolves and the liquid becomes clear. On cooling, it is reprecipitated. The substance aggregates without crystalline structure on heating, Hougounenc describes the appearance of albuminuria. On account of its solubility in acid, it is classified with the albumoses. With regard to its precise classification the substance is independent of the diet.

The solubility of the precipitate on heating and on that with potassium ferrocyanide in these tests which is like that of an ordinary albumin. In the sodium chloride solution it is formed in the cold, and dissolves on warming. The precipitate reappears. This peculiarity will be of great value in the presence of the Bence-Jones substance.

Detection and Character of the Mucin Acid in the Cold (Mucin, Nucleo- Nucleohiston)

Under physiologic and pathologic conditions, acetic acid when added to the u-

³ Deut. Arch.

precipitate. At one time it was customary to assume that the substance was mucin. More recent investigations have shown that this substance is not a true mucin, but belongs to the group of nucleoproteins. The two classes of substances are difficult to differentiate by a simple reaction. Physically, they are much alike. Chemically, they show important differences. Mucin is a glucoprotein, nucleoprotein, a phosphoprotein. The mucins do not contain phosphorus, but yield on hydrolysis a protein and a carbohydrate. The nucleoproteins contain phosphorus, and give a substance containing phosphorus (nuclein) and a protein. Mörner's¹ investigations have still further cleared the matter. He has shown that the greater number of precipitates which are thrown down by acetic acid are due to a combination of serum-albumin with chondroitin-sulphuric acid, which decreases the solubility of the albumin. According to the relative proportions of albumin or the paired sulphuric acid, the precipitate which is formed on the addition of acetic acid has the characters of serum-albumin or albumin.

Stäbelin² grouped some of the precipitates in the class of globulins. This observation was confirmed by Rostoski (*Sitzungsberichte d. Ges. Würzburg*). Matsumoto found the precipitate to consist of chondroitinogen and euglobulin. Oswald (*Zeit. ges. Biochemie*, 1904, v) found the same substances.

As has been seen, a number of substances have been found in the precipitate formed by acetic acid, and for each of them trustworthy observations are possible. It is therefore advisable, as the differentiation is a difficult one, to group them simply in the class of substances precipitated by acetic acid.

Mörner suggests the following differentiation (excluding the globulins which were not considered in his investigation). The salts are removed from a large quantity of the urine by dialysis. To every liter, 2 cc. of acetic acid are added. The precipitate is dissolved in a little water, and reprecipitated by acetic acid. It is then tested for some time with 5 per cent. hydrochloric acid on a water-bath. If sulphuric acid and a reducing substance can be detected in the liquid, Mörner considers the compound of chondroitin-sulphuric acid with protein. If no sulphuric acid can be detected, a true mucin is present. If both sulphuric acid and a reducing substance be absent, and the substance yields phosphoric acid and nuclein bases on digestion with pepsin-hydrochloric acid, a nucleo-albumin is present. These tests are not within the range of ordinary clinical methods.

Reinfeld's nucleohiston may be also precipitated by acetic acid. This substance contains phosphorus. It has been found in the urine as a result of the breakdown of leukocytes in cases of leukemia. Its identification may be made by the method of Kolisch and Burian.³

Mucin is found in the urine partly dissolved, but the greater part is in suspension. The undissolved part forms the physiologic nubecula in the urine, which is seen in the urine after it has stood some time. It is also seen in the urine, and forms a cloud. Pathologically, it is seen in increased amount in cystitis and pyelitis, and forms the so-called mucin deposit. With an increase of mucin, there is usually an increase in albumin, resulting from the breaking down of epithelium. This increases the difficulty of differentiation.

The general detection of these substances may be made with an

² Zeit. klin. Med., lii.

³ Zeit. f. k

hibit a bloody color. Of course, we must remember that after a uria urine has stood for some time many of the blood-corpuscles dissolve. Hence, we need as fresh a specimen as possible to distinguish between hematuria and hemoglobinuria.

If the urine remain in the bladder for a long time, the hemoglobin changes to methemoglobin. This is especially the case in slow bleeding of a kidney affected with parenchymatous nephritis, such as is seen in chronic hemorrhagic nephritis. In these cases the urine is more or black in color than red.

The presence of red corpuscles can be demonstrated under the micro-

(Compare Organized Admixtures and Sediments of Urine.)

Hemoglobin itself, whether dissolved or still contained in the red corpuscles, can be shown to be present in the urine by the following means:

Chemical Detection of Hemoglobin.—The different derivatives of hemoglobin which are found in the urine react alike to the chemical tests. (Compare Spectroscopic Test, p. 574.)

Heat Test.—In performing the heat test for coagulable protein (p. 574 seq.), if hemoglobin be present, a brownish coagulum will result. The test is not very delicate. In contradistinction to the protein precipitate, the coagulum tends to float upon the surface of the fluid. Mixing with alcohol and sulphuric acid will bleach the color.

Heller's Blood-test.—To a test-tube half full of urine 5 drops of potassium or sodium hydroxid are added and the mixture heated. If hemoglobin be present, a brownish-red or blood-red, flocky precipitate forms. It consists of the phosphates and carbonates of the earthy bases which have carried down with them the hematin that has been freed from the hemoglobin in the reaction. In alkaline urines the same method often produces no precipitate, because the phosphates and carbonates have already completely separated out spontaneously. The necessary quantity of phosphates and carbonates may be supplied by adding to the specimen about the same volume of a normal urine. In this test the coloring-matters which appear in the urine after the addition of chrysarobin, senna, rheum, or rhamnus may react very much like hemoglobin, and so may lead to confusion. But in the latter case a brown color which arises in the fluid portion of the specimen upon the addition of an alkali after cooling, and the decoloration upon the addition of acetic acid, are characteristic. (See p. 612.)

The test is very delicate. If the urine be dark, or be from a case of jaundice, so that the characteristic color may be missed, the precipitate may be filtered off. It is dissolved in acetic acid with a characteristic red color, which appears dichroic when reflected light, and gives the absorption spectrum for hematin. Both the precipitate or the solution may be used for Teichmann's test (see below). Hematoporphyrin also gives a red precipitate with Heller's test. The acetic acid solution does not give spectrum of hematin, but of hematoporphyrin. (See p. 545.)

Teichmann's Hemin Test.—After filtration, the precipitate from the Heller's test or, better still, the precipitate produced by a solution of tannic acid, is washed and dried in the air. Any hemoglobin that will be contained in this dried precipitate, which we employ for Teichmann's delicate test. A small bit of the dry material is placed on a glass slide with a particle of sodium chlorid, a drop of glacial acetic acid is added, a cover-slip is laid upon the mixture, and the whole is heated to the steaming-point (but not to the boiling-point) for about

one minute. A little acetic acid is added for evaporation. If the fluid turns brown, it is allowed to evaporate. Teichmann's characters (3) are then evident on microscopic examination; consist of the hydrochlorid of hematin.

The test frequently fails because excessive heat is evaporated too quickly, so that, of course, the characters disappear so readily. Very beautiful crystals are sometimes formed in the cold.

Schönbein-Almén's Turpentine-Guaiac Test.—A delicate of the blood-tests. A layer consisting of tincture of guaiac¹ and oil of turpentine is placed on the top of the urine. If hemoglobin be present, a blue line forms at the junction of the two layers, grayish blue. This test will sometimes give a positive result when the microscopic test fails. The oil of turpentine employed must be old. It may be well to test the diluted blood solution. Before performing the test the urine is acid (adding acetic acid to an a

Pus in the urine may turn the reagent blue, but appears quite as well without the oil of turpentine (owing to the oxydase content of the leukocytes. The same method as upon p. 544 (shaking with ether) for examining the sediment with the urine to avoid the above confusion.

The Aloin and Benzidin Tests.—See Examination of Urine.

Spectroscopic Detection of Hemoglobin.—In the spectroscopic test, it does not make any difference whether hemoglobin is still contained in the blood-corpuscles or whether it is free in the urine. In the urine hemoglobin undergoes various modifications—in the form of oxyhemoglobin, methemoglobin. The spectra of these substances are represented in Fig. 233.

These various derivatives of hemoglobin are often found simultaneously and so produce a mixed spectrum. In profuse hemorrhage into the urinary passage, the spectrum is that of hemoglobin. With hemoglobinuria and with true hematuria, on the other hand, we find principally methemoglobin. The spectrum, however, may be altered to reduced hemoglobin, or to bilirubin by bacterial decomposition.

For clinical purposes the spectroscopic test is performed by placing a layer of urine 1 or 2 cc. thick by transmission in a glass tube, or by reflection in a small hand spectroscope. If the urine be very dark or cloudy, it must be filtered.

When the urine contains very small amounts of hemoglobin, an acetic acid solution of the hematin-containing reagent Heller's test (see p. 573) can be used for detection. The hematin bands will be seen. This method is best when the urine is so deeply colored from the presence of bilirubin that the hemoglobin or methemoglobin spectrum is not visible.

¹ Alcoholic solution of guaiac resin, 1 : 5. The best is best used freshly prepared. The ordinary tincture of guaiac is not prepared from the resin, but from the wood of the tree. The green coating of the piece of wood is removed by boiling in water.

PLATE 3.

hmann's Hemin Crystals.

DETECTION OF HEMATOPORPHYRIN

Hematoporphyrin occurs in the urine principally after the protracted administration of sulphonal, trional, and tetronal. It is also encountered in tuberculosis and other infectious diseases, pneumonia, inflammatory rheumatism, pericarditis, Addison's disease, paroxysmal hemoglobinuria, hepatic cirrhosis, hematemesis, and lead-poisoning. It also occurs rarely under pathologic conditions about which little is known.¹ Pal² describes a case of paroxysmal hematoporphyrinuria: only when the excretion of the substance is very pronounced does the urine show the characteristic port-wine color.

It is considered to be a red pigment derived from hematin but free from iron. Nencki and Sieber consider that it is isomeric with the biliary pigment bilirubin.

It is demonstrated by Salkowski³ as follows: 30 to 50 cc. of urine are completely precipitated by an alkaline barium chlorid solution (a mixture of equal parts of a cold saturated solution of barium hydrate and a 10 per cent. solution of barium chlorid). The precipitate is washed with water and then with absolute alcohol, and the hematoporphyrin extracted by treating it with alcohol acidulated with hydrochloric acid.

The extraction is best performed by repeatedly pouring a warm mixture of 10 cc. of alcohol and 6 to 8 drops of hydrochloric acid upon the precipitate in the filter. The resulting red-violet solution gives the two bands of acid hematoporphyrin. (Compare Fig. 233, No. 6, p. 545.) Supersaturation with ammonia turns the solution yellowish, and the four bands belonging to hematoporphyrin in alkaline solution appear in the spectroscope.

DETECTION OF BILIARY PIGMENTS

The most important biliary pigments are bilirubin and biliverdin. The latter is derived from the former by oxidation in the spontaneous decomposition of bile by putrefaction, and perhaps also by ferments (oxydases). These two pigments, and more especially bilirubin, always appear in the urine whenever biliary pigment gets into the blood, *e. g.*, in jaundice (p. 42 et seq.). The oxidation products of bilirubin and biliverdin which may also appear in the urine are bilifuscin and biliprosin. These substances are not well characterized.

Icteric urine can usually be recognized by its color, which varies from a dark yellowish red or brown to a greenish black. A yellowish foam and yellowish stains of the urine upon clothes are particularly characteristic. The sediment also is usually stained yellow.

The following methods are employed chemically to demonstrate the presence of biliary pigments:

Gmelin's Test.—Filtered urine is allowed slowly to trickle down the side of a test-tube and stratify itself upon a layer of nitric acid. If biliary pigments be present, color changes occur at the line of junction of the two fluids—from greenish blue through violet red to yellow. The individual layers of urine pass through this play of colors with varying rapidity, according to their distance from the nitric acid, so that we usually see several of the colors superimposed. Sometimes the green ring is the only one we can see plainly, but this is usually enough. A red-violet⁴ alone, however, may be produced by skatol or indol coloring-matters (p. 582). Gmelin's reaction depends upon the various steps in the oxidation of bilirubin; hence, the nitric acid should contain some nitrous acid. Crude yellow nitric acid fulfils this qualification, or the

⁴ Compare below with regard to the possibility of confusion with indican.

On the other hand, the test may fail when bile-pigments are undoubtedly present. As icteric urine often becomes colored on standing in the air, one must be careful that the action of the acetic acid is in the nature of a katalysis.

Salkowski Test.—The urine is rendered alkaline by the addition of a few drops of a sodium carbonate solution; a solution of calcium chlorid (1:10) is added drop by drop, until the solution above the precipitate shows, after mixing, the normal color of the urine. The precipitate is then filtered, well washed in a test-tube with alcohol, and then dissolved by adding hydrochloric acid and shaking. If the clear solution contains bile-pigment, boiling will turn it green; if not, the fluid will not change color. The green solution will change to blue on adding a few drops of concentrated sulphuric acid, and finally to red. This test is often successful when Gmelin's test gives a negative result, and Salkowski recommends it particularly in those cases where the normal color of the urine interferes with Gmelin's test.

Reissner's Test.—A few drops of tincture of iodine are added to the urine. If bile-pigment is present, the specimen will turn a beautiful emerald green. If the tincture of iodine is diluted ten times with alcohol, and the dilution is then stratified with the urine, a green ring will appear at the line of junction of the two fluids.

Marsten's Test.¹ A mixture of 19 parts of 25 per cent. HCl and 1 part of 5 per cent. HNO₃ is allowed to stand at room temperature for from several hours to a day, until it has turned slightly yellowish. One part of this acid mixture is added to 5 parts of 95 per cent. alcohol. A few drops of urine are added to 1 cubic centimeter of this acidulated alcohol. If the urine contains bile-pigment, a characteristic green color appears almost immediately, even at room temperature. The author considers the test sensitive, but not more delicate than Gmelin's.

Reisner's Test for Cholecyanin (Bilicyanin).—Five to 10 cc. of a 20 per cent. solution of zinc acetate are added to 20 or 30 cc. urine. Sodium carbonate is added slightly to diminish the marked acidity. The abundant precipitate contains all the bile-pigments; it is washed on a filter and then dissolved in ammonia. This transforms the bile-pigment into cholecyanin. A neutral solution of the latter is blue green, and exhibits red fluorescence and a characteristic spectrum with three absorption-bands. One of these bands is in red, sharply defined and dark, between C and D, nearer to C; a second, less sharp, in yellow, between D and E; and the third, a very faint one, in green, between D and E.

Reisner's Test.—It is claimed that in urine which contains bile-pigment powdered sulphur immediately, or almost immediately, sinks to the bottom. This peculiarity is characteristic of urine which contains biliary acids. The test is not very reliable, since after a certain time some of the powdered sulphur will sink in normal urine. It is probable that the temperature of the urine has something to do with the result of the experiment, but it has not been determined to what extent.

Wiewicz's Reaction.²—One cc. of a 1 per cent. solution of sodium nitrite and 1 cc. of a 1 per cent. solution of sulphanilic acid are mixed, and added drop by drop to 10 cc. of urine. The amount added must not exceed 10 drops. The mixture turns a bright red, changing to amethyst on the addition of 1 or 2 drops of concentrated hydrochloric acid and a large amount of water. If the urine contains much bile-pigment, it should be diluted.

Microscopic Detection of Bile-pigments.—The urine must contain a sufficient amount of bile-pigment. It is acidified with hydrochloric acid and allowed to stand for some time in the cold, after which bilirubin will be precipitated as fine, microscopic needles colored intensely brown (Fig. 278, d). These needles are often observed when icteric urine is evaporated to test for the presence of leucin or tyrosin (p. 605). The bilirubin needles are, however, smaller than tyrosin needles.

Method for Removing Bile-pigment from the Urine in Order to Perform Other Tests.—The color of bile-pigment may be removed very easily either by extracting the urine with chloroform or boiling the specimen with some animal charcoal. It is necessary before testing for salicylic acid with ferric chlorid, because the tincture of iodine, like the tincture of iodine, is apt to produce a green discoloration in the urine, which hides the violet color of the iron salicylate. The urine must not be boiled too long with the charcoal, as the latter is apt to combine with the acid. It is always advisable to make a control test, in order to be sure that the process of decolorizing has not destroyed the substance we are trying to detect.

¹ *Arch. f. Physiol.*, vol. ix, p. 313; ref. in *Centralbl. f. Physiol.*, vol. xiii,

² *Münch. med. Woch.*, 1906, No. 11.

DETECTION OF

The bile acids occur in the urine (retention) jaundice. These acids are to be tested for them.

Hoppe-Seyler¹ gives the following directions: The urine is added to the urine. The resulting mixture is boiled with alcohol, and filtered while still hot. It is then dissolved in hot alcohol. A few drops of soda solution is then evaporated over a water-bath until the alcohol is nearly dry, when the sodium salts of the acids are extracted with absolute alcohol, when the sodium salts of the acids are extracted to a small volume, with excess of ether in a closed bottle. In this way they can often be obtained as crystals. But if a resinous precipitate may be dissolved in alcohol, the residue is extracted with alcohol, and the residue extracted with alcohol. The lead precipitate produced in the residue.

Tyson's process is simpler (Emerson, 1882). Fifty to 240 cc. of urine are evaporated to dryness, and the residue is extracted with absolute alcohol, and ether are added. The biliary acids are precipitated in water, and the aqueous solution decolorized.

Pettenkofer's Test.—To the urine add two-thirds of its volume of concentrated sulphuric acid, so that the mixture does not become too thick. Add 3 to 5 drops of a solution of 1 part of water, and shake, whereupon a red color is produced.

Straasburg² has at times succeeded in detecting bile acids in the urine directly by adding a small amount of fufural. To the dried filtrate is added a drop of fufural. If bile acids are contained in the urine, a beautiful red color appears in a minute in the particular place at which the fufural is added, which turns to a dark purplish red, which is permanent.

Von Udránsky considers a direct detection of bile acids in the urine. To 1 drop of urine with 1 cc. of water and 1 drop of fufural is added 1 drop of fufural thoroughly in one drop of concentrated sulphuric acid. A violet color is produced, but it is unsafe to trust to the color reaction, as the shades of color which are given by the various acids are difficult to differentiate.

Haycraft claims that his method for detecting bile acids is perfectly trustworthy. This consists in adding a few drops of concentrated sulphuric acid to the urine. In the presence of biliary acids a white precipitate is formed in five minutes. This phenomenon is produced by the emulsifying action of the bile. The test is not applicable to bile-pigments, as they possess the same property (examined for biliary acids usually contain no bile-pigments, not reacting sharply in distinguishing normal bile-pigments.)

¹ Handbuch der physiol. u. pathol. Chem., vol. i.

² Arch. f. d. ges. Physiol., vol. i.

DETECTION OF INDICAN AND INDIGO

Indican, or indoxyl-sulphuric acid, in the urine is the product of the action of proteins, and is a derivative of indoxyl, which in turn is an oxidation product of indol. This decomposition occurs in the urine normally, but is more pronounced in digestive disturbances and diminished peristalsis (intestinal obstruction). Indican may also be found under some circumstances in various other parts of the body in suppurative processes. The substances from which indol and indican are derived is probably tryptophane, which is formed in the digestion of proteins. Indican is always present in the urine in small amounts.

An increased amount of indican in the urine is of some diagnostic importance in helping to locate the seat of an intestinal obstruction. Experience has shown that an *obstruction in the small intestine* is quickly indicated by a marked increase in the amount of indican in the urine, as contrasted with an *obstruction in the large bowel*, where there is very little or no such increase, unless perhaps in the later stages. This is probably because the trypsin of the pancreatic juice favors decomposition and the formation of indican. Both factors aid each other in the decomposition of the proteins. In deep-seated obstruction in the small intestine the stagnation of the contents, which favors decomposition, occurs primarily where trypsin is no longer active. (The latter, as is well known, is destroyed or reabsorbed in the course of the intestinal passage.)

In obstruction in the small intestine the stagnation takes place where the trypsin favors the decomposition. A further explanation is that the greater portion of the proteins which furnish the indican have already been absorbed in the large intestine.

Besides interference with the permeability of the intestine, one may find increased indican excretion in enteritis, typhoid, and especially in perityphlitis (perityphilitis). The condition of the patient is in inverse proportion to the amount of indican in the urine.

Increased indican is also found in tuberculous conditions, not only when associated with the breaking down of tissue, but in tuberculous meningitis and adenitis. Whether this is directly connected with the tuberculous condition or is due to an associated disturbance of digestion cannot be said. The former seems to the author to be possible, for indicanuria has been found in patients in whom the digestion was apparently normal. This observation seems to have a certain amount of diagnostic value.

Constipation only causes indicanuria when putrefactive processes take place. Indicanuria is not found in simple chronic constipation. In this condition resorption is usually above normal.

A certain amount of diagnostic significance is attached to the appearance of indicanuria in conditions in which protein is being broken down in other parts of the body than the intestinal tract. To this class belong tuberculous conditions mentioned above. Increased indican is also found in gangrene of the lungs, putrid bronchitis, and empyema. It is, however, not safe to assume the formation of pus from this sign, for the author has observed a pronounced indicanuria in tuberculosis with a scanty exudate, associated with hyperpyrexia.

If the duct of the pancreas be occluded, the amount of indican in the urine will be diminished. However, as the indican in the urine is normally quite small in amount, or even absent altogether, a dimi-

nution can be clinically significant of a duct only under conditions which would o of a large amount of indican, *e. g.*, jaundic

cent. solution of basic lead acetate, in order to precipitate those substances prevent the shaking out of the indigo by the chloroform. After removing the acetate by filtration, he adds an equal volume of fuming concentrated hydrochloric acid, which contains 4 gm. of ferric chlorid to the liter. The mixture is then shaken. The reaction will take place, he claims, within a few moments, and the indigo may then be extracted with chloroform. Obermayer believes that this method is adapted for an accurate colorimetric determination of the amount of indigo present.

Amann's Test.—J. Amann¹ recommends sodium pyrosulphate ($\text{Na}_2\text{S}_2\text{O}_7$) as an oxidizing reagent. He claims that this reagent also will not cause any loss of indigo by excessive oxidation. The test is performed as follows: To 20 cc. of urine are added a few drops of pure sulphuric acid, 5 cc. of chloroform, and then 1 cc. of a 10 per cent. solution of sodium pyrosulphate. They are mixed gently for several minutes (too much shaking may produce an emulsion). The chloroform is then allowed to settle and will be colored blue by the indigo. The method is utilized for an exact colorimetric determination.

Huber's Test.²—A test-tube is filled with 1 volume of the urine and 2 volumes of hydrochloric acid. Two or 3 drops of 1 per cent. osmic acid solution are added, and the mixture shaken. The urine is colored in a few minutes violet to blue. The indigo may be shaken out with chloroform. Osmic acid may further change the indigo to a colorless substance. Highly colored urines may be clarified with basic lead acetate.

Other oxidizing reagents often produce a more or less distinct indication of indigo, e. g., nitric acid in the test for bile-pigments. (See p. 575.) The employment of nitric acid for the detection of indigo there is dangerous because of decolorizing the indigo. It will be recalled that the oxidation of indigo is one of the reactions of nitric acid, which is why it is not a reliable agent for the detection of indigo.

As already mentioned, *indican* is sometimes oxidized spontaneously to indigo in the urine before or after being voided. Urine which contains indigo presents a black, green, or bluish tint. All that is necessary to prove that the color is due to indican is to shake the urine with chloroform and then allow the latter to settle, when it will be seen to be turned blue. The needle-shaped or thin, plate-like crystals of indican may sometimes be detected microscopically in the urine sediment or even in the residue of the dried chloroform extract.

PRESENCE AND DETECTION OF PHENOL

Traces of phenol in the form of phenyl sulphuric and phenol glycuconic acids are normally present in the urine. After the administration of salicylates, the amount is largely increased, and this is more pronounced if absorption through exposed surfaces has occurred from the use of salicylic dressings. Pathologically, phenol is increased in the urine in increased intestinal putrefaction and in pus-formation. Brieger³ believes that fever itself causes an increase. An observer claims that the amount of indican excreting from typhoid allows one to judge of the fever occurring in the intestine, and that the presence of phenol points to an intestinal infection. The amount of phenol in the urine and the approximate amount of indican are given on p. 611. The blackish green color of indican is described on p. 555.

For the detection of indican see p. 643.

¹ *Ann. Chem. Phys.*, 1897, No. 6, p. 499.
² *Ibid.*, vol. xxxiii.

ROSENBACH'S REACTION (RED U)

Rosenbach¹ has described the test. Nitric acid is added drop by drop to the urine, which is being continually boiled. The urine acquires a red color, while the foam produced is of a reddish or brownish-red color without being particularly distinctive, as it may be due to the continued addition of nitric acid. With the continued addition of nitric acid will turn yellowish red or yellow with a yellowish tinge. If soda or ammonia drop by drop is added, which dissolves in an excess with the urine. In these cases the urine is sometimes brownish, sometimes a slight reddish tinge of brown, and sometimes acid while the specimen is still colored brownish principally—although perhaps not entirely brownish—indigo-red (indirubin, indigo-purpurin or indican. (See p. 579.) It may be due to the oxidation of skatol pigments by means of nitric acid. Indigo is often produced in the reaction. The test has a diagnostic value in the indican reaction.

DETECTION OF MELANIN (PHYMA)

A peculiar brownish-black coloring-matter (melanin), sometimes appears, partly as a sediment in the urine of patients suffering with melanuria. The urine contains melanin is blackish. Exposure to the action of nitric acid or ferric chlorid, will turn it still darker. Indurubinogen exhibits a dark color only after the melanin is converted into melanin. The addition of bromine water also produces a dark color. An excess of bromine water is added, and throw down a dense dirty-yellow precipitate. Nitric acid will, under certain circumstances, may be confounded with indigo, and melanin. The solubility of indigo in chloroform, and the solubility of melanin in ether, can differentiate them.

UROROSEIN (UROERYTHROGEN)

A red color is not infrequently noticed in the urine after the addition of mineral acids, especially hydrochloric acid, and in many conditions of disease. Nephritic urine contains a pigment which they called *urorosein*, the color of the urine. It is probably identical with the pigment which is evidently differs from indigo-red, and may be contrasted to Rosenbach's reaction (indigo-red). The addition of alkaline carbonates to the urine, which is insoluble in chloroform and ether.

UROERY

This pigment occurs in normal urine, and in the urine after quantities of food and alcohol, and after the use of pathologic urines in digestive disturbances. It is the pigment which is responsible for the color of the sediments. It was formerly regarded as identical with indigo, but to be a different substance. Urines containing this pigment are of a decided orange color. When concentrated, a carmin-red color is produced;

¹ Berlin. klin. Woch.

pigment first to a purplish blue and then to a green. These reactions obtain with pure solutions of the pigment, however, and such solutions are difficult to obtain. The coloring-matter is soluble in amyl alcohol and bleached on exposure to light.

DETECTION AND OCCURRENCE OF UROBILIN AND UROBILINOGEN

Urobilin is in all probability a derivative of bilirubin. Modern investigations have, however, cast doubt upon the old assumption that it is identical with hydrobilirubin. Urobilin occurs in small amounts in normal urine, but, according to Sallet, not until the urobilinogen has been acted upon by light. The normal yellow color of the urine is due to urobilin, but to urochrome.

Technically, the detection of urobilinogen has the same significance as that of urobilin. According to the investigations of F. Müller, urobilins are formed from biliary coloring-matters in the intestine. Whether they can be formed directly from the coloring-matter of the blood is not known. Hildebrandt describes a case in which there was total obstruction of the ductus communis choledochus and a severe jaundice. It was the resorption of an enormous hematoma. During this time there was no urobilin in the urine or other fluids of the body. He concludes that neither the liver nor the other processes of metabolism are able to transform the coloring-matter of the blood directly into urobilin. It is, however, questionable if this is so in all cases.

Pathologically, urobilin is found in increased amount in many cases of jaundice (urobilin jaundice). The conditions for this are that bile reaches the intestine (F. Müller). One also finds a large amount of urobilin in all affections associated with the breaking down of red blood cells, as in fever, scurvy, internal hemorrhage, and pernicious anemia. It was at one time assumed that the urobilin was a direct transformation product of the breaking down of blood coloring-matter. It is now believed that the urobilin is formed from the biliary coloring-matters, as is normally the case, and is only excreted in the urine because in these cases the liver is incapable of transforming it to biliary pigment. (Disruption of the intermediary circulation of urobilin between the liver and the intestine.) This is in accord with the modern view that in all cases the jaundice, which was previously assumed to be hemato-genous, is also a sequel of insufficiency of the liver.

This view makes doubtful the diagnostic significance of the presence of urobilin in the urine as showing an internal hemorrhage. It was formerly thought that the blood coloring-matters were transformed into urobilin and hematoïdin, and were excreted as urobilin. Hence the detection of this substance was thought to indicate cerebral hemorrhage, hemorrhagic infarcts, retro-uterine hematocele, and extra-uterine pregnancy with internal hemorrhage. It must be noted that in all these cases a disturbance of the liver is not excluded, especially when the condition is associated with fever. For the recognition of cerebral hemorrhage the detection of urobilin in the urine loses much of its significance, as differentiating that condition from softening. Most of the hemorrhages of the brain are too small to cause a distinct increase of urobilin in the urine. The larger hemorrhages are too rapidly fatal to

Hildebrandt, *Zeit. f. klin. Med.*, 1906, vol. lix, has shown that the excretion of urobilin is not directly associated with fever, but is a result of conditions associated with hyperpyrexia, such as a severe infection or a toxemia.

show urobilin in the urine. The expected at a time when the difference and hemorrhage has more theoretic of the brain, the fever which accor urobilinuria.

DETECTION OF

The most accurate method for the of urobilin is by means of the spect urine with a little hydrochloric acid tinct. Acid urobilin solutions, when v absorb the entire blue end of the s green. On the other hand, a thin lay shows an absorption-band between gr trast to urobilin, the biliary pigme diffusely. A simple chemical metho of urobilin is as follows: The urine is ammonia, filtered, and a few drops of a solution of zinc chlorid are added. A if urobilin be present.

To demonstrate chemically a very urine it must be first extracted by ge acidulated with a few drops of hyd volume of amyl alcohol. When the a it will be colored brown. If the lay alcohol portion remain cloudy, like an clarifying may be aided by the additio Several drops of an alcoholic amm Dzondii) and some 1 per cent. alcol then added to the amyl alcohol laye shows the presence of urobilin.

Hildebrandt recommends as being with zinc acetate. The reagent is an zinc acetate and 90 parts of absolute before using. Equal parts of the re and the precipitate which is formed amount of urobilin the filtrate show either directly or after the addition of the characteristic absorption-bands. is that the large amount of zinc salt other urinary substances which inter rubin in the urine does not interfere amount of bilirubin in the urine, Sch by adding to the urine one-quarter of chlorid solution, neutralizing carefully the precipitate containing the biliary

whether the urobilin, as characterized by the above-mentioned tests, is a substance, or whether there exist several urobilins, has been recently much discussed.¹ A final verdict is not yet possible. In any case a differentiation (suggested by Jolles) of physiologic and pathologic urobilins has not been sufficiently worked out to be of any clinical value. Hildebrandt has recently returned to the view that urobilin is a definite chemie substance.

Tests for Urobilinogen

Hildebrandt uses the Schlessinger test described above, by allowing the urine and reagent to stand for twenty-four hours in order to effect the conversion of urobilinogen into urobilin. If the fluorescence is only to be observed after the urine has stood, urobilinogen is alone present. If a fluorescence is obtained at once, which increases after twenty-four hours, both substances are present in the original urine. **Paradimethylamidobenzaldehyd Reaction.**—O. Neubauer² showed that the reaction which was first described by Ehrlich was due to the presence of urobilinogen. Pappenheim had demonstrated that the substance was constantly present in urobilin. Clemens, Thomas, and Hildebrandt are those who have done the most with this reaction.

According to Hildebrandt,³ the reaction is carried out as follows: 20 gm. of paradimethylamidobenzaldehyd are rubbed up in a mortar with 100 cc. of concentrated hydrochloric acid, more acid added, until the volume is 500 cc., and then the mixture made up with water to 1000 cc. Two drops of the reagent are added to the urine. If the urine contains urobilinogen, it becomes dark red in color, and shows a color between D and E. Occasionally the red color only appears some minutes or after the urine has been heated. The spectroscopic examination is absolutely necessary for the test.

Thomas has shown that the "bright yellow" reaction which occurs with the test described on p. 607 is due to urobilinogen. The reaction is less delicate than the paradimethylamidobenzaldehyd reaction.

QUALITATIVE DEMONSTRATION OF GRAPE-SUGAR (GLUCOSE; DEXTROSE)

Preparation of the Urine for the Qualitative Test for Sugar

" ably occur in every normal case. We have this absolutely, but we do not do so than before fermentation by the yeast. On the contrary, be demonstrated, in the first place, discrimination of glucose excretion (*diabetes mellitus*). No sharply defined line between these two. *Glycosuria* accompanies cerebral and digestive affections, after the use of monoxid, chloral hydrate, and the presence of glycuronic acid, mercuric sublimate, amyl nitrite, nitro-glycerine, and hunger. It sometimes occurs in people temporarily excrete sugar after ingestion of sugar or of other substances (*glycosuria*).

In cases of alimentary *glycosuria* those attributable to undue consumption indicate some grave disorder, because of the excretion of sugar, probably for the reason

Pföger's Arch., vol. lxi, pp. 623—Hopkins, Jour. Physiol., vol. xx,

München, 1903, H. 2.

that the absorption of starch takes place much more rapidly than that of sugar. Excessive starch ingestion gives rise to sugar excretion as related to diabetes mellitus, and reserve the term "glycosuria" for cases where the starches can be converted into sugar and excreted, but where excessive ingestion of sugar produces glycosuria. As a matter of fact, excessive ingestion of sugar does not produce glycosuria in perfectly healthy individuals.

Urine containing much glucose is pale and has a pale color combined with a high specific gravity. The amount of urine is usually, although not always, pale urine, excreted in excess of the normal amount. The specific gravity of 1030 or more, allows of the diagnosis of diabetes mellitus. Urine containing glucose may be recognized either from the development of a precipitate or from the microscopic demonstration of crystals. Therefore sugar tests must always be performed.

To detect a small quantity of glucose in the urine, it is better to select for examination a specimen of urine voided a short time after eating, because the quantity of glucose in the urine is at a maximum. If the meal was rich in carbohydrates, it is more liable to obtain a positive result. (It is to be noted that apparently perfectly healthy people, by the abundant consumption of these two foodstuffs, may produce glycosuria in such a degree as to be considered as on the border-line between health and disease.)

If the urine contain protein, this must be removed by tests for sugar. (See p. 566.) If it contain hyaline casts (p. 555), this compound may be removed by shaking and filtering.

Almost all the qualitative tests for sugar in the urine are based upon the precipitation of the sugar with lead acetate. About 5 cc. of lead acetate solution are added to 50 cc. of urine; the mixture is filtered, and the filtrate is treated with sodium phosphate, this solution being added until the solution becomes turbid. The decolorized filtrate is then employed for the purpose of the test, since various substances which interfere with the reactions have been removed. The original urine should also remain acid after the addition of the sodium phosphate. If precipitated from an alkaline urine by the addition of sodium phosphate, it should be finally insured by the addition of several drops of acetic acid. Urines should be diluted with 2 or 3 volumes of water if certain substances which interfere with the reaction are present.

An appropriate preparation of the urine for the treatment with mercuric nitrate, as recommended for examination.

Glucose may be detected in the urine by the following tests:

Moore-Heller's Test

A few cubic centimeters of potassium dichromate solution are added to about three times this volume of urine. If considerable sugar be present, the mixture becomes turbid as a result of the oxidation of the glucose. The principle upon which this test is based has not yet been

is absolutely characteristic of sugar only when the color be-
dark brown or, at least, yellowish brown, or, with a diluted urine,
dense clear yellow. The test is rather delicate, a characteris-
action being obtained even with a considerably diluted diabetic

Unless the result is absolutely certain, it is a good plan to com-
the reaction with that obtained from a normal urine, and in doubt-
ses even with that from a diluted urine. If the mixture of dia-
urine and potassium hydroxid be allowed to cool, and is then
usly acidulated with sulphuric acid, an odor of burnt sugar should
veloped.

Reduction Tests

Fommer's, or the Copper Test.—One-third the volume of
ium or sodium hydroxid is added to the urine in a test-tube, and
drop by drop a solution of cupric sulphate (1 : 10), the mixture
shaken constantly until a slight excess of the precipitated cupric
oxid remains undissolved. If sugar be present, we can add a good
more of the cupric sulphate solution without producing a precipi-
and the mixture will turn a beautiful blue color. This depends
the fact that in the presence of glucose the formation of an easily
e double combination takes place, which holds much more cupric
oxid in solution. The blue color does not, however, positively
the presence of sugar, because it also occurs if the urine contain
in or tartrates, or if ammoniacal decomposition has set in. Urine
contains protein also holds some cupric hydroxid in solution, but
violet color is produced. If we heat this dark-blue solution just
ling in the presence of sugar, cuprous hydroxid ($\text{Cu}_2(\text{OH})_2$) and
s oxid (Cu_2O) separate in greenish-yellow clouds, which grad-
turn brick red and finally diffuse throughout the fluid. This is
the fact that glucose has the power, in alkaline solution, to reduce
hydroxid to cuprous hydroxid and cuprous oxid. These separate
a yellow to brick-red precipitate,¹ and the liquid becomes decolor-
If a large amount of sugar be present, metallic copper (Cu) may
separate out upon the side of the test-tube in the form of a brown-
l coating.

positive and typical copper reaction certainly permits no doubt in
l to the presence of sugar in the urine, for no other substances
in the urine which can furnish in every detail a corresponding
on. At most, in some individual instances, it is only necessary to
guish whether it is glucose or some other reducing carbohydrate
s present, and, from the much greater frequency of glucose, it is
ally safe to attribute a positive copper test to it. To be perfectly
n that the reducing action is due to glucose, the test must always
regard to the differentiation between
the recognition of the copper-reducing
ear more or less abundantly after the

l formation, compare p. 611 et seq.

id is brick red. The more alkaline the solu-
color, the oxid taking the place of the yellow

If the copper reduction be less typical as to whether the urine contains glucose in virtue of the presence of uric acid or glycuronic acid, does reduce copper, differentiate a reaction due to glucose. One of the above constituents of the urine should be noted: If the reduction be complete, must not only be decidedly decolorized, but a distinct granular precipitate of cuprous oxide. On the contrary, the reduction by no means complete, the immediate formation of a yellow precipitate is produced merely a dirty yellowish precipitate of salts, and other substances keep in solution the cuprous oxid which is formed. It does often require leaving the test to stand for some time in order to bring down a yellowish-red precipitate. Suggestive of glucose. The above distinguishes a reduction is in reality a quantitative test. It keeps a much larger amount of cuprous oxide in solution, able still further to reduce this soluble cuprous oxide cannot remain in solution. It is evident from the difference between urine containing sugar and urine contain less than 0.2 per cent. of sugar, as in normal urine without precipitate, cuprous oxid will remain in solution, such slight amounts of sugar simply produce turbidity. Yet even in these cases (where of some diagnostic importance) that the reduction is intense, clearer, and in a measure more typical of urine, very likely because the fluid is more concentrated, suboxid, despite the fact that it remains in solution. Trommer's test produces a clear yellow precipitate, the red suboxid usually appears a shade of red. Attention to these facts, an expert can recognize atypical reactions in recognizing a reaction which has been influenced by the difference of the normal urinary constituents. Trommer's test at a temperature of 60°C. is a certain method in doubtful cases, because the normal constituents do not reduce to any notable extent. It is easily obtained by first boiling the urine, and then adding a volume of cold potassium hydroxid, and heating to boiling.

To make Trommer's test as delicate as possible, as much cupric oxide as possible in solution, should be added. This end is attained by continuing to add cupric sulphate until a precipitate is formed. On the other hand, too much should not be added, as cupric hydroxid, when heated with potassium hydroxid, forms cupric oxide, and so vitiates the test.

The delicacy of the test may sometimes be increased by diluting the urine containing sugar two to five times. This is done by adding an equal volume of the urine to dissolve the suboxid and vitiates the test where the undiluted urine gave no reaction.

ion will not produce any change, because the slight trace of cuprous oxid formed will remain in solution in spite of the dilution.

Another method of improving the delicacy of Trommer's test is to shake the urine with finely powdered animal charcoal, and finally filter. The animal charcoal evidently retains certain substances which dissolve the suboxid and prevent precipitation.

Seegen's modification of Trommer's test can be recommended for the detection of small quantities of sugar. It depends upon the fact that animal charcoal adsorbs glucose while in solution, and that the latter can be washed out of the charcoal again. Seegen makes a thin paste with purified animal charcoal and the urine to be examined. A few minutes later this paste is poured upon a filter. If the urine has filtered through, he washes the charcoal remaining upon the filter with as much water as he employed urine, and then repeats the process. The filtrate of each washing is kept separate, and Trommer's test is performed upon each of these filtrates. The substances which cause the solution of the cuprous oxid are retained in the carbon much longer than will the glucose. Frequently the test succeeds best with the second or third wash-water, as the first may contain a large amount of the substances which dissolve the suboxid. This method is very much more sensitive for urine which contains only a slight amount of sugar than Trommer's test upon the urine itself. Seegen claims that a positive reaction is absolute proof of the presence of sugar, because the second or third wash-water from a normal urine no longer reduce.

The copper test may also be performed with *Fehling's solution*, such as is used for quantitative determinations. (See p. 619.) This should be freshly prepared before use; it consists of equal parts of solutions I and II. The test should be performed as follows: About 5 cc. of urine are first boiled in a test-tube, and then cooled for about twenty seconds; then about 1 cc. of Fehling's solution is added. If sugar be present, the reaction appears immediately. The reason we allow the urine to cool off to about 60° or 70° C. is because at that temperature normal urine no longer reduce. If an insufficient amount of copper be added, the cuprous oxid which is formed will not become precipitated, but will remain dissolved in the urine solution. In such an event the test must be repeated with an increased amount of Fehling's solution. Fehling's solution possesses no particular advantage in the qualitative test; on the contrary, the selection of exactly the amount of solution to procure a maximum precipitation of cuprous oxid is much more difficult with this than it is with Trommer's test, where the least excess of cuprous oxid is easily recognized by the appearance of undissolved cupric hydroxid.

It is important to remember that albumin in the urine does not interfere with the reduction of the cuprous oxid, but it does interfere with the precipitation of the red suboxid. For this reason the albumin should be removed from the urine before performing the test. It is equally important to perform all the tests in the presence of the ammonium carbonate and the yeast, because the fermentation will also prevent the precipitation of the cuprous oxid.

It is recommended and the above precautions should be taken in all the most practical and safest tests for the detection of sugar. Only a large amount of salts of glycuronic acid can lead to a false negative result. In regard to the appearance of the lactone, it should be remarked that after successful reduction the glucose disappears from the urine, and the combined glycuronates present. This is distinguished from dextrose by the reduction. In doubtful cases the test should be repeated as controls, particularly Almén's and Rubner's test.

Böttger's Test).—The original Böttger test is performed with bismuth subnitrate, $\text{NO}_2\text{Bi}(\text{OH})_2$ by the glucose

Phenylhydrazin Test (Fischer-v. Jakach)

Five drops of a concentrated solution of lead acetate are added to about 10 ml. of urine, and the precipitate filtered off; the filtrate is acidified with a drop of acetic acid; phenylhydrazin hydrochlorid, the size of a pea, and a piece of sodium the size of a bean, are added. The mixture is heated for about a half-hour in a water-bath and then allowed to cool.

If glucose be present, a yellow precipitate separates out upon cooling. This consists of characteristic microscopic aggregates of needle-like crystals of phenylglucosazone (Fig. 236). If the precipitate be not crystalline or of a yellow color, or if the crystals are not of the form represented in the accompanying plate, we must

The test is very delicate and even sufficient to detect small amounts of sugar in the urine. As a matter of fact, it is not infrequently positive, as under certain conditions the normal urine gives a positive reaction. Besides, there is a source of error in the determination of the melting-point of the precipitate, which may be obtained, but this is too

This is also the best method of distinguishing between the various carbohydrates which, though they all give a positive result in performing the phenylhydrazin test, it is not infrequently possible to distinguish them from the urine.

The test is simplified by Cipollina¹ under Salkowski's

ing substance in question is some carbohydrate. Either Rubner's phenylhydrazin test, or the fermentation test will answer this question. The last mentioned is one of the surest and most convincing sugar tests, and should be resorted to in all doubtful cases. It is upon the fact that the addition of yeast to any urine which contains fermentable sugar produces a decomposition or fermentation, the carbohydrates are transformed into alcohol and carbon dioxide. Proof of the fermentation is obtained by demonstrating the presence of the carbon dioxide. (Concerning the conclusions as to the type of carbohydrate, see p. 594 et seq.)

The fermentation test is performed as follows: A test-tube is filled to the brim with urine, a piece of ordinary compressed yeast 'the size of a pea' is dropped in, and the tube is then gently shaken until the yeast is divided, without allowing any air to enter. The tube is closed with a perforated cork which carries a V-shaped piece of glass tubing (Fig. 37, b). The test-tube is then inverted, placed in a beaker, and in some moderately warm place (best, 25° to 30° C.). If the urine

order to detect the presence of fructose, Seliwanoff's reaction may be used. Urine is added an equal volume of concentrated hydrochloric acid containing in the following proportion: 0.5 resorcin, 30 cc. water, and 30 cc. concentrated hydrochloric acid. If a Burgundy-red color occur after heating, the presence of fructose may be suspected. The test is not, however, perfectly convincing.¹ It has suggested that the color be extracted with amyl alcohol after neutralizing with sodium carbonate, and the alcoholic solution examined spectroscopically. Dilute solutions give an absorption-band in the green region of the spectrum between the lines E and B. More concentrated solutions show a second band of blue at F. The color may be extracted from the alcohol by repeated extraction with water. The alcohol then becomes yellow in color. The red color of Seliwanoff's reaction must appear at once, for on continued heating other carbohydrates give the same reaction. Fructose may be formed from glucose in this manner. According to Guiart and Grimbert, the formation of a precipitate soluble in alcohol after cooling is characteristic for the presence of fructose.

If the urine contain β -oxybutyric acid, besides glucose and fructose, the detection of the three is more complicated. The polarimetric and titration estimations are in disagreement, and after fermentation the urine is still levorotatory. The levorotation after fermentation is not sufficient to account for the difference between the results obtained by polarization and the estimation by titration.

The presence of paired glycuronic acids in the urine which not infrequently occurs in diabetic urines, and which also rotate the plane of polarized light to the left, may complicate matters. Compare the detection of glycuronic acids, p. 597.

According to Strauss and Raspide, alimentary fructosuria is an important diagnostic sign of disease of the liver. Raspide (Thesis, Toulouse, 1903) found in 92 per cent. of cases of disease of the liver an alimentary fructosuria when the fasting urine was given 60 gm. of fructose in 200 cc. of water. The results are, however, questioned by the fact that in purely functional affections of the liver one obtains only a transient fructosuria. The excretion of fructose may be detected one to three days after its ingestion.

Prevalence and Detection of the Pentoses.—Pentoses are carbohydrates, each of which contains 5 atoms of carbon, or some multiple of five. They have been found repeatedly in diabetic urine, but frequently also in urine without glucose.² Pentosuria was first observed temporarily as so-called alimentary pentosuria after the ingestion of large quantities of fruits which are rich in pentoses, such as plums, huckleberries, and also after beer. In other cases, on the contrary, the excretion of pentose is chronic and independent of the quantity and nature of the pentoses in the ingested food. In these cases there is a specific pentosuria recognized by Neuberg as optically inactive arabinose. The amount of pentose in the urine may vary between 0.1 and 1 per cent., so that the daily quantity excreted can never exceed 20 gm. A theory for this pentosuria is still quite uncertain. But pentosuria certainly bears no relation to diabetes mellitus. Bial³ has described pentosuria as a hereditary anomaly. The demonstration of pentose in the urine is clinically important only because an erroneous diagnosis of diabetes mellitus may be made. This is all the more important since it has been observed that patients with pentosuria are injured by a rigid diet which does not influence the amount of excreted pentose in the slightest. Urines containing pentoses give a reduction with Trommer's and Nylant's tests.⁴ They are optically inactive, and do not ferment with yeast. They show the following reaction:

Seliwanoff's reaction is commonly employed for the detection of pentoses. Seliwanoff describes it as follows: A little phloroglucin is heated in 5 to 6 cc. of fuming hydrochloric acid, care being taken to leave a slight excess undissolved; the solution is divided into approximately equal parts. To 1 portion $\frac{1}{2}$ cc. of the urine to be examined is added; to the other portion $\frac{1}{2}$ cc. of normal urine. Both specimens are warmed over a water-bath. It is advisable to decolorize both specimens

entose. The results of investigators of this reaction are not in agreement as to its diagnostic importance in diseases of the pancreas. (See Eichler, *Med. klin. Woch.*, June 24, 1907; Elöesser, *Grenzgebiete der Med. und Chir.*, 1907, p. 111.)

DETECTION OF GLYCURONIC ACID

Glycuronic acid is formed in the body, probably even under physiologic conditions, by the oxidation of glucose, from which it differs but little in its elemental composition. It appears in the urine when an opportunity is furnished for it to become combined in the organism with other bodies, and so to escape excretion. There are a great many substances which may combine with glycuronic acid. Among them are chloral hydrate, morphin, camphor, oil of turpentine, salicylic acid, saccharin, santonin, thallin, chrysophanic acid, menthol, most phenols and phenol derivatives, i. e., indol, skatol, naphthol, etc. Flückiger¹ has proved that, aside from the uric acid and kreatinin contained, the reducing power of normal urine depends upon the presence of the paired combinations of glycuronic acid, especially the phenol, parakresol, indol, and skatol glycuronates. Flückiger² has more recently confirmed these observations, and in addition has shown that the excretion of the combined glycuronates has a bearing upon diabetes mellitus and upon alimentary glycosuria. He claims that after excessive ingestion of carbohydrates, and especially of glucose, large quantities of the glycuronic acid are sometimes excreted in human urine before sugar appears. In these cases it is as if the organism were able to oxidize the ingested sugar up to the stage of glycuronic acid, but no further. This hypothesis of the origin of glycuronic acid will explain the frequently coincident occurrence of combined glycuronates and glucose in the urine which has been observed both in alimentary glycosuria and in diabetes mellitus. Here a part of the glucose which is not utilized has been converted only to glycuronic acid. Glycuronic acid is capable of reducing, but not of fermenting. This explains the peculiarity which has been observed in the urine of a diabetic patient upon a successful diet, i. e., it still reduces but does not ferment. The reduction is peculiar in that, unlike the glucose reduction, it occurs very slowly (see below). Many discrepancies between the quantitative estimations of the amount of sugar by the polarization, by the fermentation, and by the copper reduction can thus be explained by the simultaneous presence of glucose and some combined glycuronates. The latter, unlike the sugar, rotate to the left, but like it, they reduce.

Glycuronic acid has never been found in the urine except in combination. Flückiger claims that these combinations can be split up by boiling for one to five minutes with 1 per cent. H_2SO_4 and that the peculiarities of the combined and of the free glycuronic acid can be examined in the urine. The duration of heating for each combined glycuronate by demersol is different in the maximum manner expressed.

employed to detect the combined gly-

curonic acid. Since the combined glycuronates only reduce after prolonged heating. If we boil the urine beforehand, by H_2SO_4 in order to cause the cleav-

ing of the glycuronates, will enter into combination with the hydrazin test, employed for demonstration of aldehydes, will give a negative result if we employ the glycuronates; but, on the contrary, the test by first boiling the urine with

demersol does reduce alkaline copper solutions, in spite of its reducing power, and fermentation will produce an incom-

plete reduction, while the combined glycuronates, on the other hand, give no reduction of glycuronic acid this levo-rotation after boiling with H_2SO_4 (see above).

¹ Stäubli, Deut. Arch. f. klin. Med., 19

An excellent résumé of the whole subject will be found in the article Magnus-Levy, in the *Ergebnisse der inneren Medizin und Kinderheilkunde*, 1908, Springer, Berlin; also Ewing, *Arch. Int. Med.*, 1909.

By acetonuria in the clinical sense is understood an increased excretion of acetone in the urine, which may be suspected from the odor which the urine possesses, and also by the sweetish odor of the breath. Magnus-Levy believes that the greater part of the acetone does not occur preformed in the urine but is the result of the breakdown of aceto-acetic acid while passing for acetone.

The test for acetone can first be made with the urine itself. If the test is negative, the urine should be distilled. Acetone is very volatile so that the distillate will be much richer in acetone than the original urine and smaller quantities can be detected.

Distillation can be performed without any complicated apparatus in the following way: About 50 cc. of urine acidified with a little phosphoric acid (sufficient for a marked acid reaction, to prevent foaming) is poured into a fractionation flask (Fig. 238) and heated to gentle boiling, preferably over a water-bath and under a wire gauze. A test-tube is

slightly tilted for collecting the distillate. The test-tube is now closed and will now collect in the test-tube without shaking. Within a few minutes several cubic centimeters of distillate will collect, and the acetone test can then be performed.

Fig. 238.—Fractionation flask.

If no acetone is present, the distillation will not show an event. Another method must be used if the urine is rendered slightly alkaline and shaken with water, and the test performed.

One of the following tests is usually

used. A little Lugol's solution¹ is added to the urine to produce an intense black precipitate which will gradually disappear if acetone is present, a yellowish sediment conceals the precipitate. It can be recognized by its color. It contains 2 gm. iodine, 1.8 gm. potassium iodide, 30 cc. water, and ammonia, one may use tincture of potassium iodide (1 part iodine, 2 parts

acid will discharge the yellow color, and the solution will become red or violet. This test may lead to the erroneous supposition of presence of acetone if the urine contain parakresol (von Jaksch). The one which is usually recommended for the direct examination is without distillation; but, according to the author's experience, it is in that case very delicate, and he does not recommend it. If distillate be used, however, the test is a useful one, and has recently been recommended by Studer.

In order to avoid confusion with aldehyd, Le Noble and Lee suggest the use of ammonia instead of potassium or sodium hydroxids.

Lange's Test.—Lange¹ suggests a ring test as a modification of Le Noble's and Le Noble's tests, and which appears to be more delicate. 1 cc. of the urine are mixed with 0.5 to 1.0 cc. of acetic acid, and a drop of a freshly prepared concentrated solution of sodium nitroprusside is added. The mixture is overlaid with ammonia. At the point of contact a characteristic intense violet ring is formed. The color spreads gradually and spreads in the course of time through the mixture.

DETECTION OF ACETOACETIC ACID (DIACETIC ACID) ($\text{CH}_3\text{COCH}_2\text{COOH}$)

Acetoacetic acid does not occur in the urine of healthy individuals on an ordinary diet, except, perhaps, in very small quantities. As S-Levy has pointed out, most of the acetone found in the urine is in the form of acetoacetic acid, and hence the acid is to be observed in the same class of cases as acetone itself: in fasting, in diabetes mellitus, on a meat diet, fever, dyspeptic conditions, etc. It is usually possible to detect acetone simultaneously with acetoacetic acid in the urine. If acetoacetic acid be formed, it is all transformed into acetone; if not, then both substances will be found in the urine. It frequently happens that the mother substance of diacetic acid, β -oxybutyric acid, is present. Diaceturia, like acetonuria, also bears some relation to the metabolism of the carbohydrates, since in the diaceturia of non-diabetic individuals the proteins are decomposed without the simultaneous oxidation of the carbohydrates, and it may frequently be suppressed by the administration of carbohydrates. The excretion of a large amount of acetoacetic acid by a diabetic upon a mixed diet, like the excretion of acetone under the same circumstances, is an indication of a severe stage of the disease. Such diaceturia is favored by a rigid meat diet, and may frequently be diminished by the ingestion of carbohydrates.

Do not assume that diaceturia has a definite relation to state that acetonuria is a distinct condition. It may be noted that the appearance of acetoacetic acid is usually accompanied by an increased elimination of β -oxybutyric acid.

According to Lange (p. 653), the amount of acetoacetic acid in the urine is proportional to the amount of β -oxybutyric acid. The ratio for acetoacetic acid does not always remain constant. This must be remembered when regulating the diet in diabetes mellitus.

Acetoacetic acid can be demonstrated as follows:

Barfoed's Chlorid Reaction.—One or two drops of a 1% solution of barfoed's reagent are added to the urine. If diacetic acid is present, a white precipitate is formed.

¹ Woch., 1906, No. 36.

acid be present, a Bordeaux-after filtering off the precipitate quantity of the ferric chlorid must be employed after the by filtration. Thiocyanates, thallin, kairin, and other aron color. For this reason the psumed only after positive resting control tests:

DETECTION

β -oxybutyric acid does not s Levy). Its presence is associated acetone and aceto-acetic acid (Se tein diets, in diabetes mellitus, in associated with decreased utilizatio oxybutyric acid are the fats and the formation of the acid are discusse der inneren Medizin und Kinderhe

In diabetes mellitus a consid suggests the onset of acid intoxica

β -oxybutyric acid appears to l there also (see above).

Unfortunately, the process fo plicated. The acid must first be oxybutyric acid be formed.¹ This

¹ For a detailed description see and xxi, and Kütz, *ibid.*, or Kütz, 2

In cases of diabetes mellitus we may, therefore, suspect the presence of β -oxybutyric acid if the amount of glucose, as determined by titration, is distinctly less than that obtained by the polariscope. Protein must, of course, be absent, as well as β -oxybutyric acid, is levogyrate. Levulose may lead to confusion. Külz first removes the protein from the diabetic urine, next the sugar by titration (which will also dispose of the levulose), then decolorizes by precipitation with lead acetate and ammonia, and finally examines with the polariscope. If this process the urine still exhibits a tendency to left-handed rotation, β -oxybutyric acid is in all probability present. To be certain we must exclude the possibility of combined glycuronates. The latter condition must also be fulfilled before we assume the presence of β -oxybutyric acid from the left-handed rotation. The ethereal extract obtained from the fermented urine which has been strongly treated with phosphoric acid.

Goldvogel's Test.—Three hundred cc. of the suspected urine are evaporated to 100 cc. A similar test is made with a normal urine. To each evaporated urine is added 10 cc. of 10 per cent. sodium hydroxid solution. Both are very vigorously stirred with a glass rod. Normal urine does not froth, while a specimen containing β -oxybutyric acid gives a distinct soapy foam. This test only indicates the presence of β -oxybutyric acid in the urine.

An almost positive proof of the presence of β -oxybutyric acid in cases of diabetes mellitus is the detection of acidosis, as shown by a considerable increase in the quantity of ammonia excreted in the urine. (See p. 651.)

A distinct advance has been made in the last two years in the methods used for the determination of acetone, acetoacetic acid, and β -oxybutyric acid through the investigations of Folin and of Shaffer.¹ The methods, which are complementary to one another, depend upon the fact that—(1) acetone is removed completely from the urine by a current of steam if the urine be saturated with sodium chlorid; (2) acetoacetic acid is completely converted into acetone by heating with acids; and (3) β -oxybutyric acid is converted into acetone by treatment with an oxidizing agent. The one employed is potassium bichromate and sulphuric acid. When one removes successively the acetone due to preformed acetone, acetoacetic acid, and oxidizes the residue, one may obtain the acetone formed from β -oxybutyric acid. The analytic procedure is much less complicated than those of previous methods, and gives more definite results. We are now in a position to study problems of acidosis with methods which lend themselves to routine use.

The methods are as follows:

Acetone.—Folin's Method.—The same apparatus is used in this method as is used in Folin's method for ammonia. The procedure is as follows: 25 cc. of the urine to be examined are introduced into a cylinder, and 10 drops of phosphoric acid, 10 cc. of sodium chloride solution, and a little kerosene to prevent emulsion are placed in the cylinder. 150 cc. of water, 10 cc. of potassium permanganate solution, and 10 cc. of decinormal iodine solution are added. The cylinder is closed and a current of air drawn through it for twenty to twenty-five minutes. All the iodine is converted into iodide in the absorption flask and is converted into acetone. 10 cc. of concentrated hydrochloric acid are added in excess of the amount required by the iodine. A brown iodine color will be produced. The excess of iodine is removed by sodium thiosulphate, using a solution of starch as an indicator. The decinormal iodine solution which has been used for the removal of acetone.

As determined by Hart's modification of Folin's method in the foregoing test may be employed. After the acetone has been removed from the urine, the urine is heated in a water-bath, another absorption flask is used with a fresh iodine solution. The current of air is

not concerned in acidosis see Ewing, Arch.

run for twenty-five minutes, during which the acetone is carried over with the air that due to acetoacetic acid.

β -Oxybutyric Acid.—*Shaffer's Method.*—Take 100 cc. of the urine to be examined. The presence of β -oxybutyric acid in the urine is suspected if a strong ferric chlorid reaction is given. If the reaction is desirable to use an amount of the reagent that will give a strong reaction. An excess of basic lead acetate is added to the urine, and ammonium hydroxid. One must ascertain the amount of lead. On filtering, a few drops of the reagent are added. The contents of the flask are diluted to 200 cc. with water. Transfer 200 cc. of the filtrate to an 800 cc. flask, add 10 cc. of concentrated sulphuric acid and a little more water so that 250 cc. have passed over. This distillate is then mixed with acetone and acetoacetic acid in the flask. The residue from which the distillate was obtained is added to 500 cc. of water and 0.5 gm. of potassium dichromate is added to the residue by means of a glass rod. The liquid distilled over is replaced by water so that the flask kept constant. Under no circumstances should a green color, showing that the potassium dichromate is reduced. If this be the case, more bichromate is added. After about 500 cc. of distillate has been obtained, add about 20 cc. of hydrogen dioxid, 3 per cent. solution of potassium hydroxid. This is now the residue. Twenty-five or 50 cc. of decinormal iodine solution is added, 10 cc. of a 40 per cent. solution of potassium iodide is added, well and allowed to stand for five minutes. The mixture is then titrated with a solution of sodium thiosulfate until the mixture is colorless. The amount of iodine absorbed by the acetone present in the urine. Each cubic centimeter of β -oxybutyric acid.

The results in all these three methods are compared.

DETECTION OF ALKAPTON (HYDROQUINON)

The substance which has been named alkapton has the property of becoming extremely dark when exposed to air, turns a dark to brownish-black color when exposed to light. Urine stains upon the clothing. Urine containing alkapton reacts positively to the ferric chlorid test. Urine containing sugar by its inability to ferment, and by the green color given by the solution of ferric chlorid. It is also precipitated by Millon's reagent, but can be brought out again by adding a lemon-yellow precipitate.

The chemical nature of alkapton was determined by Wolkow's² investigations have, however, shown it to be hydroquinon, and regard it as such. Only in one case were they able to detect lactic acid or uroleucinic acid. Alkapton is a disease of the body with any discomfort, and has general occurrence in an apparently healthy individual with dysuria. The etiology of the disease is unknown. The homogentisic acid appears to be quantitatively increased. The subject is discussed by Wolkow³ and also by Langstein and Meyer.⁴ Alkaptonuria is an anomaly of intermediate character between the protein of the food and the

¹ Millon's reagent is made by dissolving 10 gms. of picric acid in 100 cc. of nitric acid (specific gravity, 1.42). The solution is then filtered after standing some hours.

² Deut. Arch. f. klin. Med., vol. lx

of the organs. A further review of the subject will be found in an article¹ in which are discussed the views put forward by Albrecht, Zdarek, Osler, and recently by A. Wagner, regarding the connection between alkaptonuria and the pigmentation of the joints which was called ochronosis by Virchow. L. comes to the conclusion that, as in cystinuria, alkaptonuria is a disturbance of metabolism in which, in the former, the aliphatic groups of the protein molecule are affected, and in the latter, the aromatic. According to Embden, this takes place in the liver. Neubauer and Falta have shown that all aromatic compounds are capable of combustion in the body increase the amount of alkapton in the urine. This is not the case with normal individuals.

The experimental relationship between alkaptonuria and ochronosis has been established by Gross and Allard,² who have shown that cartilage allowed to stand in a solution of homogentisic acid, the substance excreted in the urine in alkaptonuria, was stained deep black by the acid. Wagner³ demonstrated in a recent paper that the cartilages of a case of alkaptonuria showed ochronosis.—[W.]

DETECTION OF LEUCIN AND TYROSIN

A considerable quantity of leucin and tyrosin in the urine is always diagnostic. They are nearly always in solution. Their presence is

be separated by recrystallization in a little alcohol, in which leucin is more soluble than tyrosin. Tyrosin gives a red color on heating with Millon's reagent (See foot-note, p. 604)

In a case of acute yellow atrophy in the author's clinic the following procedure suggested by Heffter was successfully employed. Two hundred cc. of urine were treated with basic lead acetate as long as a precipitate was formed with the reagent. The excess of lead was removed with hydrogen sulphid, the lead sulphid filtered off, and the solution evaporated to about one-third to one-fourth its original volume. On cooling, the tyrosin separated out and was filtered off. It responded to the Denigés-Mörner test. The leucin can be obtained by further evaporating the filtrate.

Rüttimeyer has also observed the reaction in pulmonary actinomycosis.

The diazo-reaction must be considered as a metabolic symptom of certain diseases, which, like splenic swelling and fever, is not of diagnostic value in itself, but only when considered in connection with the other symptoms. It should also be noted that a similar reaction may be obtained after the administration of opium, morphin, heroin, dionin, tannic acid, alcohol in large quantities, chrysarobin, naphthalin, phenol, cresol, creosote, and guaiacol. The fact must consequently be borne in mind before drawing conclusions as to the diagnostic value of the diazo-reaction.

The so-called *egg-yolk reaction*, as described by Ehrlich, is said to be somewhat characteristic of pneumonia just before and during the crisis. It is a preliminary reaction, i. e., a diazo-reaction which occurs before the addition of ammonia. The urine becomes deep yellow after the addition of the reagent, the color showing most distinctly in the foam. It does not turn red when ammonia is added, but becomes lighter yellow. Oppenheim found it constantly in 28 of his cases at the crisis. In some conditions we might predict the crisis from this reaction. Ehrlich attributes it to urobilinogen, a transition product of the bilirubin arising from the hemoglobin of the hemorrhagic exudate, and this assumption has been confirmed by the investigations of Thomas. (See p. 585.) The egg-yolk reaction is less sensitive than the paradimethylamidobenzaldehyd reaction for urinobilinogen described on p. 585.

EXAMINATION OF THE URINE FOR SUBSTANCES INTRODUCED INTO THE BODY FROM WITHOUT (DRUGS AND POISONS)

DETECTION OF LEAD

placed in the urine and left acid and then tested accordingly. If the urine contains but a small amount of lead, a larger quantity of the urine must be used. To 10 cc. of hydrochloric acid and potassium chlorate, and the lead sought for in the urine. A small amount of urine is evaporated to dryness, 20 per cent. hydrochloric acid is added, and the residue is heated on the water-bath until the fluid no longer contains lead. Another portion of 3 gm. is heated until the fluid no longer contains lead. If the liquid is allowed to cool, and examined for lead with hydrogen

IV

hydrochloric acid (Fürbringer). The urine is placed in a flask with $\frac{1}{2}$ to $\frac{1}{4}$ gm. of potassium chlorate, washed first with water, then with a glass tube of high melting-point at the upper end. It is there heated. The mercury, which is volatile and will be de-

posited as a mirror at the capillary end of the tube, the deposit will be colored. (In reference to other methods, see Späth, 1)

DETECTION OF

Iodin occurs in the urine as potassium iodid or one of its preparations as follows: A few cubic centimeters of urine are added about the size of a pea until the latter is dissolved. A 1 per cent. sodium nitrite solution is added, the mixture is treated with sulphuric acid. If iodine be present, a blue ring is formed at the line of junction of the two liquids. The color is due to the iodine liberated from the potassium iodid by the nitric acid and the blue iodid of starch.

Another way is to add to the urine 1 cc. of a 0.5 per cent. sodium nitrite solution¹ and shake gently. If iodine be present, the chloroform layer is colored a rose red to violet, due to the solution of iodine in the chloroform.

To prove that a patient has really taken one or two of potassium iodid into the prescribed dose, the urine and the saliva are tested with the desmold and glutoid tests. (See pp. 433 and 434.)

Both the above tests are very delicate. In the presence of a slight trace of iodine, the chloroform test may set free indol and skatol pigments as a result of the reaction. But in this case the chloroform is colored reddish. But in this case the chloroform is more deeply colored than the chloroform. To help in deciding in such a case, because the reaction may be simulated by an indican reaction, for instance, only calcium hypochlorite, but sometimes even the change. Here, however, it is easy enough to see that the change is capable of producing this blue ring without the addition of starch.

Palladium chlorid furnishes still another method of detecting iodine. To contain iodine is strongly acidulated with 1 cc. of a moderately saturated solution of palladium chlorid. If iodine be present, a brown discoloration or precipitate. This reaction has but one meaning, the starch or the chloroform reaction.

DETECTION OF

The test for bromine is performed in exactly the same manner as the test for iodine, with chloroform, except that a few drops of concentrated hydrochloric acid are used to liberate the bromine. The chloroform will be colored yellowish brown by the bromine. The test, less delicate than the iodine test, is sufficient to detect a therapeutic ingestion of large doses of bromine salts. In the test, we must remember that the chloroform is not the urinary coloring-matters. To prevent the urine, to which have been added 2 cc. of concentrated hydrochloric acid, are incinerated, the ash dissolved in water and tested for bromine, as above.

A. Jolles² has described an admirable test for bromine upon the fact that bromine can be freed from its compounds in acid solution, and that such free bromine gives a brown color to *indamin*. Filter-paper is moistened with a solution of *p*-dimethylphenylendiamin, dried, and then acidulated in a narrow-necked flask with potassium manganate. The color is now a permanent brown.

¹ The author previously suggested compound potassium nitrite, which frequently contains iodine, the above reaction.

² This solution is prepared by adding 1 gm. of *p*-dimethylphenylendiamin to 10 cc. of concentrated hydrochloric acid, allowing it to stand for a day, and then adding enough hydrochloric acid to make it acid.

³ Wien. klin. Rundschau, 1898, No. 12.

paper is suspended in the neck of the flask, and the latter is warmed over a water-bath. If bromin be present, the paper will be colored from violet, through blue and green, to a brown. Iodin and chlorin present other brownish shades different enough not to be confusing.

The demonstration of bromin in the urine is of no special interest, except, of course, in verifying a diagnosis of suspected bromism.

DETECTION OF SALICYLIC ACID AND SALOL

Ferric chlorid is added, drop by drop, to the urine. In the presence of these compounds the solution becomes more or less violet. The test is delicate and can be used for control after the administration of these substances. The salicylic acid is partly eliminated as salicyluric acid, which gives the same reaction. To distinguish between salicylic acid and aceto-acetic acid see p. 602. For the detection of salicylic acid in urine containing bile-pigments, see p. 577.

DETECTION OF PHENOL

Phenol appears in the urine largely as phenol sulphuric acid. Ferric chlorid will produce a violet-blue color in the distillate from a phenol urine to which 5 per cent. sulphuric acid has been added. With saturated bromin water, a precipitate of tribromphenol is produced. Millon's reagent gives a red color on heating. The last reaction is given by a number of other substances. According to Salkowski, the following short method may be used to detect phenol. A control test must be made with normal urine. The urine is heated to boiling in a test-tube with nitric acid. The urine gives off an odor resembling oil of bitter almonds due to the formation of orthonitrophenol. When the urine is perfectly cold, bromin water is added. A precipitate will be formed of tribromphenol. Normal urine treated in this way will remain clear or give a very faint opalescence. A second portion which has been boiled with nitric acid is made alkaline with sodium hydroxid. With urine containing phenol an orange-red color is produced to orthonitrophenol sodium. Phenol urine turns dark to black upon exposure to the air. This is due to the fact that it contains hydroquinone and pyrocatechin, which form dark-colored derivatives upon oxidation.

pigment, and frequently the only one, is urochrome; it holds a close chemic relation to urobilin, into which it may be converted by cautious oxidation. According to Klemperer, the normal color of the urine corresponds approximately to 0.15 per cent. urochrome solution. He determines the amount of contained urochrome colorimetrically by comparison with a solution of "Echtgelb" (Leitz). Klemperer prepares this solution for comparison by dissolving 0.1 gm. of dry "Echtgelb" in a liter of water, and diluting 5 cc. of this solution to 90 cc. According to Klemperer, the shade of this solution of "Echtgelb" (1: 180,000) corresponds to 0.1 solution of urochrome, and by diluting the urine or the test solution, the quantity of contained urochrome may easily be determined by the colorimetric method. The urine and the test solution must, of course, be contained in vessels of the same shape when the comparison is made. Stronger solutions of "Echtgelb" cannot be employed, since their color does not agree with that of urine. Should the urine contain considerable quantities of other pigments, such as urobilin or hematoporphyrin, an exact colorimetric estimation of the urochrome is, of course, impossible. Klemperer, nevertheless, believes that if the presence of these other pigments is not disclosed by absorption-bands in the spectroscopic examination (urochrome absorbs light diffusely), the method given above will be sufficiently accurate. He also believes that the estimation of the daily excretion of urochrome furnishes an indication of the functional activity of the kidneys, since he assumes that urochrome is formed in the kidneys. It is, nevertheless, clear that if the latter assumption be incorrect, and it has not yet been proved, the amount of excreted urochrome is not of such simple significance, since it would not depend upon the kidneys alone, but also upon the unknown function upon which the formation of urochrome in the body is dependent. The fact that pale urine is frequently excreted in uremia could also be due to the fact that, in addition to the impairment of the excretory function of the kidneys, other important functions holding some relation to the formation of urochrome are also implicated.

QUANTITATIVE ESTIMATION OF PROTEINS. ESTIMATION OF TOTAL ALBUMIN (SERUM-ALBUMIN + SERUM-GLOBULIN)

ESTIMATION BY OBTAINING AND WEIGHING PURE (COAGULABLE) PROTEIN, OR BY KJELDAHL'S METHOD

An exact quantitative estimation of coagulable protein must depend upon a complete precipitation of the protein by boiling after the addition of dilute acetic acid (2 per cent.) and the addition of $\frac{1}{10}$ volume of saturated sodium chlorid solution, which facilitates the coagulation of the protein. (See Removal of Protein from Urine, p. 566.) The precipitate must then be washed, and dried upon a dry, weighed filter at 110° to 120° C. to a constant weight, the dried residue weighed, and the weight of the dry filter subtracted. To save time in drying the precipitate, the amount of urine should be small, so that the weight of the dry protein will not exceed 0.2 to 0.3 gm. (preliminary estimation). (See below, Estimation of Quantity of Protein According to Esbach.)

Proteins are exceedingly hygroscopic; hence, the weighing should be very carefully carried out. The material should be placed between watch-glasses, with the ground edges carefully applied to each other. For very great accuracy the albumin precipitate must be first washed with alcohol and ether, in order to remove the fat before drying, and finally the content of ash determined and subtracted. With urines containing a large amount of albumin, Salkowski recommends precipitating a measured volume of the urine with 10 to 20 volumes of 95 per cent. alcohol, heating the mixture on the water-bath. The precipitate is collected on a filter and washed with hot water. The procedure is then the same as above. The amount of protein in the precipitate may be estimated by hydrolyzing the precipitate by Kjeldahl's method, and multiplying the amount of nitrogen found by 6.3. This gives the amount of protein.

gives practically identical values with those obtained by weighing the albumin. If the urine contains less than 0.002 per cent., the method is uncertain, and one uses the diaphanometric method of the same author.

DIAPHANOMETRIC METHOD OF DENIGÉ

A standard albumin solution is prepared, by obtaining a urine containing at least 0.2 to 0.4 per cent. of albumin. The amount contained is exactly estimated by weighing. The urine is so diluted that it contains exactly 0.1 per cent. of albumin. Sodium fluorid and thymol are then added to preserve it.

In 5 test-tubes of the same size, which are marked at 10 cc., and which are labeled 1, 2, 4, 8, 12, are placed 0.1, 0.2, 0.4, 0.8, 1.2 cc. of the standard solution, and the tubes filled to the mark with water or urine free from albumin. In a similar tube to the standard tube one places 10 cc. of the urine to be examined. To all the tubes one adds 2 cc. of a 5 per cent. solution of sodium metaphosphate and 5 drops of sulphuric acid. The tubes are agitated and placed in a water-bath, and heated to boiling for five minutes. After taking from the water-bath they are wiped dry and a comparison of the tube containing the urine to be examined made with the standard tubes. The intermediate amounts may be estimated. If the urine contains more than 0.012 per cent. of albumin, it must be diluted for comparison.

ESBACH'S ESTIMATION OF PROTEIN

This method consists in determining the volume of protein which is precipitated from a definite amount of urine by a certain solution.

by one-half saturation with ammonium sulphate. A portion of the twenty-four-hour amount of urine is neutralized with ammonia or with sulphuric acid and filtered. Fifty cc. of the filtrate are measured off, and to this filtrate 25 cc. of a saturated solution of ammonium sulphate (specific gravity, 1.252) added. The precipitate is allowed to stand over night. The precipitate is then filtered off and washed with one-third saturated ammonium sulphate until the washings do not show the slightest trace of coagulation with heat. Both filtrate and wash-water are collected, and by adding one-third of the total volume of saturated ammonium sulphate, half saturation is secured, and the pseudoglobulin precipitated. This is allowed to stand and filtered off. This is washed with one-half saturated ammonium sulphate. If one wishes to estimate the remaining albumin, the filtrate is made acid with acetic acid and coagulated by heating. This is filtered, washed, and weighed. The first two precipitates are digested with water for a long time, to bring them into solution; acetic acid is added, and coagulation effected by heating. The process used is that of Emerson.

In amyloid kidney and in orthostatic albuminuria the globulins appear to be the principal constituents of protein present in the urine. According to Oswald, euglobinuria is the mildest form of albuminuria, and it is also often found in the larger quantity in febrile conditions. In the acute stages of parenchymatous nephritis much euglobulin is excreted.

F. A. Hoffmann¹ describes an albumin-protein quotient which is formed from the relation of serum-albumin to globulin. In acute nephritis this has a certain amount of diagnostic value, because with the relief of the patient the quotient rises. The prognosis is better the higher the quotient. This, however, only holds for acute nephritis. Similar results have been obtained by Lecorché and Talamon.

QUANTITATIVE ESTIMATION OF GLUCOSE

In diabetes mellitus the amount of sugar in the urine generally ranges from 4 to 5 per cent., but it may be as high as 10 per cent., so that in the course of twenty-four hours 1 kg. or more may be excreted.

REGARDING THE NECESSITY OF THE CLINICIAN MAKING QUANTITATIVE ESTIMATIONS OF GLUCOSE

The author cannot lose the present opportunity of pointing out to the clinician the importance of carrying out the determinations of glucose in his own laboratory.

As to the convenient methods which are now in vogue, even of qualitative tests, which are made in hospitals, and similar institutions, have often led to the most harmful results. The examinations are made by assistants who are untrustworthy, and consequently

Furthermore, no information is given as to the results. In allowing this very important part of a clinician's work to be done by assistants, the clinician lays himself open to very great mistakes, compared to a physician turning over the auscultation to a percussor or auscultator, and giving a diagnosis. He believes that in those cases where reports are made by assistants, the clinician himself is the one who should make the necessary control tests for pentoses, and the mere statement of a report of "traces of sugar" is not sufficient. At these latter substances have been taken into consideration where the estimations are carried out by assistants. He should assure himself of this—a precaution which is very recently seen a case where a trusting physician, a diabetic with the strictest diet, and thus reduced his sugar, subsequently ascertained that the report which was given in every respect erroneous. If the physician is to be of any use, he should carry out the quantitative part from the gain in the trustworthiness of his results. But that in order to obtain the best results, a quantitative examination of the urine of the patient should be made, and one may follow instantly any change in the

ESTIMATION OF THE QUANTITY OF GLUCOSE BY TITRATION

Fehling-Soxhlet's Method

-Glucose will reduce cupric oxid in an alkaline solution to cuprous oxid. This property is the one most frequently employed in titrating for sugar, because when certain conditions are maintained, the reduction of the alkaline cupric oxid solution by the sugar takes place quantitatively. *Fehling's solution* is the one generally employed. It is prepared as follows: 34.64 gm. pure crystalline copper sulphate, 173 gm. Rochelle salt (sodium potassium tartrate), 100 cc. sodium hydroxid solution of specific gravity 1.34, distilled water up to 1000 cc.

Fehling's solution cannot be preserved in its original form. It is, therefore, advisable to keep two separate solutions, which should not be mixed until just before using. Solution 1 contains 34.64 gm. of copper sulphate dissolved in 500 cc. of distilled water, acidulated with a drop of concentrated sulphuric acid. Solution 2 contains 173 gm. of Rochelle salt with 100 cc. of NaOH solution (specific gravity 1.34), and the volume made up to 500 cc. with water. By mixing equal volumes of these solutions, a fresh Fehling's solution can be obtained for every test. This mixture contains sufficient cupric oxid, so that 10 cc. of the solution, when diluted five times with water, will be reduced to the red cuprous oxid when boiled with 0.05 gm. of grape-sugar (or, according to Soxhlet, 0.0473 gm.). If the urine contains more than 1 per cent. of glucose, it should be diluted with water, before titration, until it does not contain more than that amount. The above-mentioned rules for approximately estimating the amount of sugar from the specific gravity can be used as the basis for this procedure. As a rule, more than 5 cc. of urine are required to reduce the 10 cc. of Fehling's solution. Albuminous urine must be freed from protein by boiling the acidified urine and filtering before titration. (See p. 566.)

Method: 5 cc. of solution 1 and 5 cc. of solution 2 are mixed in a small flask, diluted with water up to 50 cc., heated to boiling, and the urine, appropriately diluted, added a few drops at a time from the buret. The mixture is kept boiling gently until it is approximately decolorized, and an abundant precipitate of the red cuprous oxid has appeared. We cannot, of course, expect to obtain accurate results with this method (Fehling's original method), because the end-reaction cannot be recognized accurately, and because a portion of the suboxid always dissolves in the ammonia liberated from the urine and becomes reoxidized. This test really gives only approximate values.

For accuracy, Soxhlet's modification should be resorted to. He pours the approximate amount of urine into the boiling Fehling's solution at once (he also uses 10 cc. of Fehling's solution diluted to 50 cc. with water), then allows the solution to boil for two minutes, and then takes the flame away. The shining meniscus at the upper margin of the fluid is his index of the end-reaction. If this persists in being still slightly blue, he repeats the test with a fresh and slightly larger volume of urine and fresh Fehling's solution until he determines the exact amount that is required to decolorize the fluid, as shown by the meniscus.

The calculation of the result is very simple. If 9 cc. of urine diluted ten times are required to reduce 10 cc. of Fehling's solution, then 0.9 cc. of urine contains 0.05 gm. of glucose.

$$0.9 : 0.05 = 100 : X$$

$$X = \frac{5}{0.9} = 5.5 \text{ gm. of grape-sugar}$$

—i. e., the urine contains 5.5 per cent. of glucose.

Or if we employ the exact figures of Soxhlet:

$$0.9 : 0.0473 = 100 : X$$

$$X = \frac{4.73}{0.9} = 5.26.$$

Various other modifications of Fehling's test have been suggested to overcome the difficulty of sharply determining the change of color of the solution, i. e., the end-reaction.

Practically speaking, Soxhlet's method is the only safe one for the practitioner; the others require especial practice and skill, otherwise they are too uncertain. It is well to note here that many if not most of the old results from Fehling's method were probably inaccurate; hence, we should be on our guard against accepting them unreservedly. The methods depending on the number of drops of urine which will decolorize a copper solution are suggested from time to time. These methods are absolutely unreliable and should never be used.

Glucose Titration According to Klimer

Klimer¹ has published Drechsel's method of titration. It seems to offer a sharp end-reaction. In the presence of guanin the red suboxide which unites with guanin to form a less readily oxidized compound so that in titration with Fehling's solution to which has been added the solution may be filtered off from copper.

This method is accurate, but only when very accurate. It is rather expensive. The details of the method are given by Klimer, Bern, 1898.

Pavy's Sugar Titration, as Modified

The difficulties with the Fehling estimation and its modifications, some of which prevent the precipitation of a sharp end-reaction. The best known modification is that of Pavy. Ammonia is added to the solution. The change in color is sharp. The principal difficulty in the reaction is the evolution of gas on boiling, which, if sufficiently prolonged, ammonia is retained in the solution to prevent the precipitation of the cuprous oxide. With the access of air also the colorless solution is oxidized. Modifications have been made by Pavy, Moritz, and others.

Recently the author has modified the method to make it more concentrated than that of Pavy.² By using 10 cc. of the solution one may boil long enough without the cuprous oxide. The solution does not need to be boiled vigorously, a glass beaker can be done with a microburner and an asbestos filter. The addition of the urine should be made when the solution falls below the boiling-point. The titration is then very accurate.

Solutions Used.—Although it has been assumed that the solution is stable, it appears to the author that the same object is not attained as to Fehling's solution, which is well known not to be one solution. For this reason the author prepares the following composition:

1. Copper sulphate crystals.....
Distilled water to.....
2. Sodium potassium tartrate.....
Potassium hydroxid
Ammonia (specific gravity, 0.88)....
Water to

The solution is made by mixing 5 cc. of Nos. 1 and 2 of the original Pavy's solution and corresponds to 10 cc. of the original. To check the correctness of this solution with a standard solution of glucose. This is done by weighing out a definite amount of glucose and performing a titration. The glucose must be dried. As pure glucose is more difficult to obtain it is recommended that pure cane-sugar be inverted and the sugar is dried at 100° C for an hour and 0.25 g of the sugar is added to 50 cc. of 2 per cent. citric acid solution and boiled. The sugar is changed to glucose and fructose. After the addition of potassium hydroxid and made up to 250 cc. In titration is obtained, which corresponds exactly to a reducing activity.

The Titration.—Five cc. each of solutions 1 and 2 are added to 75 to 100 cc., and 30 cc. of water added. The color

¹ "Ist Zucker ein normaler Bestandteil des Harns?" and "Zwei neue klinische Methoden der quantitativen Zuckerbestimmung." I. A. D., Bern, 1898.

² Physiologie der Kohlehydrate, Deuticke, 1898.

³ Deut. med. Woch., 1905, No. 36.

board with a burner which can be regulated. The urine (if it contains albumin is freed from this substance) is diluted and placed in a buret. The flow of urine from the buret is best controlled by a screw pinch-cock.

In order to secure exact results the urine must be so diluted that the amount necessary for the complete reduction of the Pavy's solution is a fairly large amount. On the other hand, the amount must not be so large as to decrease the concentration of alkali in the solution. The urine is added drop by drop, or in small amounts at a time, taking care that the boiling is never interrupted. The amount added may be more rapid at first. Toward the end of the reaction the urine should be added more slowly, as the reaction is slower at this time. The end-reaction is usually very easily observed. The flask is best held over a sheet of white paper. For clinical purposes the author has recently modified the process, avoiding the use of a buret. For this purpose 10 cc. of the urine or the diluted urine are placed in a measuring cylinder accurately graduated, and the urine delivered into the flask with a fine pipet. The amount delivered is ascertained from what is left in the cylinder after the titration.

The Dilution of the Urine.—The best results are obtained when the amount of urine necessary for decolorization is between 5 and 10 cc. This corresponds to a sugar-content of $\frac{1}{4}$ to 1 per 1000. Control estimations with the polarimeter have shown that the results are accurate. Hence, the urine should be diluted to give a titration within these limits. To do this one must make a preliminary titration in order to find the content of the undiluted urine. This preliminary titration must be carried out with great care with urines containing much glucose, in order that the end-reaction is not overstepped. With a urine containing about 5 per cent., a dilution of 1:50 is necessary. Some of the less important details concerning the operation are given in the author's original paper.

Errors in the Method.—As it is necessary to dilute the urines of severe diabetics, one must ascertain whether this dilution has an effect on the accuracy of the method. With dilutions of 1:50 the error in titration is multiplied by that factor and might seriously vitiate the results. The presence of other reducing substances than glucose in the urine also influences the results, but experiments made by Ryser in the author's laboratory have shown that the results do not influence the practical use of the method. Pavy's method has also been used by Kumagawa and Suto in another modification and has been found to be accurate. The form of the method which the author has given above is the only one which—(1) permits performance without any very great practice; (2) is simple and quick.

Lehmann's Iodometric Titration Method for Glucose¹

In this method a definitely measured amount of urine is boiled with Fehling's solution [just as in Soxhlet-Allihn's (below).—Ed.] and the copper which remains in solution in the filtrate is titrated. This is accomplished by adding a measured amount of potassium iodid solution of a definite concentration to the filtrate acidified with sulphuric acid. Iodin, which is set free according to the equation $2\text{CuSO}_4 + 4\text{KI} = 2\text{K}_2\text{SO}_4 + \text{Cu}_2\text{I}_2 + \text{I}_2$, is then titrated with sodium thiosulphate, using starch paste as an indicator. Every atom of free iodine corresponds to one atom of copper in the solution. As this method is very perfectly replaced by the author's modification of Pavy's method, reference to the details of its performance is made to the original papers and to the former edition of this book.

Titration of Glucose According to Gerrard Williamson

This is a similar method to that of Fehling, but the difficulty of the end-reaction is avoided by added ferrocyanid of potassium. Burroughs Wellcome and Co. have made up tablets containing the necessary reagents. The directions for performing the test are given with the tablets.

SOXHLET-ALLIHN'S METHOD OF GLUCOSE ESTIMATION² AS MODIFIED BY AMBÜHL

This is a thoroughly accurate method, perhaps the most reliable of all, and certainly to be recommended for scientific investigation. It is rather too compli-

¹ Arch. f. Hygiene, vol. xxx, and Zeit. f. anal. Chemie, 1898, part 4, and Pharm. Post, 1898, No. 30. Cf. also E. Riegler, Zeit. f. anal. Chemie, 1898, part 1, and Benjamin, Deut. med. Woch., 1898, No. 35, p. 552.

² Jour. f. prakt. Chemie, Neue Folge, 1880, vol. xxii, p. 52.

cated for the practising physician, but in a clinical apparatus is once put together, it may be performed. In this method a definite excess of Fehling's solution and a definite volume of urine, after filtering off the solution, the cuprously formed is collected upon an asbestos filter, and the resulting metallic copper weighed, from which the amount of sugar contained in the urine can be calculated. Ambühl, by weighing the cuprous oxide directly without reduction, the method is less suitable for clinical purposes than the above, it is not described in detail. A full description of this work.

COLORIMETRIC ESTIMATION

Because of the blue color peculiar to combination with copper, and the blue color of copper combination, made an effort to utilize this color in one way or another in colorimetrically the quantity of glucose in the urine. In our experiments, and will briefly report the results.

A conceivable method is to add to a constant amount of copper sulphate solution, which is always in excess, i. e., when, subsequently, the copper cannot be held entirely in solution, but to cause a precipitate of cupric hydroxide. Urine is added in measured quantities, and the precipitate is filtered off by means of an asbestos filter. The intensity of the color is determined colorimetrically and the quantity of the sugar estimated. The test-solution may be diluted and compared with a test-solution in a sealed tube. It has, however, been proved that the intensity of the color proves to be quite independent of the amount of sugar added, giving the impression that only a small quantity of blue combination. For instance, we found that if a 0.5 or a 1 per cent. solution of sugar was added to cupric hydroxide and copper sulphate.

Another method of colorimetric estimation is to add copper sulphate solution drop by drop from a burette to a mixture of sodium hydroxide and of the urine to be examined, until the solution commences to separate as cupric hydroxide. The intensity of the color is determined colorimetrically, but, just as before, the intensity of the color is independent of the amount of sugar. In these experiments, solutions hold in solution about an equal amount of sugar, one may not draw conclusions as to the quantity of sugar from the volume of copper sulphate solution necessary for precipitation.

One might endeavor to utilize the reduction of copper by forming the reduction (Sohlet-Allihn, p. 621) a quantity of non-reduced copper in the filtrate might be determined iodometrically. Even this method is not reliable, the color-intensity of Fehling's solution with constant amount of salt does not run parallel with the amount of copper reduced.

However, the following method of utilizing the color of the solution gives approximate results. The test is the same as above, after filtering off of the reduced cuprous oxide, for iodometric determination, or the reduced copper is not determined by weighing, but the asbestos filter until the red oxide is dissolved. The intensity of the color is determined colorimetrically, and the quantity of copper contained in the filtrate is determined colorimetrically by comparing with a copper solution of known intensity. A solution of copper nitrate, so as to have exactly the same color as the solution of copper, and so have exactly the same color as the solution utilized in preparing Fehling's solution.² Two test-tubes of equal diameter are placed respectively some copper solution and some cuprous oxide solution of the nitric acid solution of cuprous oxide.

¹ Ambühl, *Chemikerzeitung*, 21, I. Sem., p. 137.

² This is explained by the assumption that the intensity of the color of the copper ion which is present in equal quantities, or, in both solutions.

darker of the two solutions until the shade of color of the two is the same. The amount of copper contained in the two solutions is then proportional to their volumes, so that it becomes possible to estimate not only the amount of copper reduced, but also the amount of sugar in the urine, inasmuch as we know just how much glucose corresponds to each cubic centimeter of the copper sulphate solution. This method of employing graduated cylinders only, and without accurate colorimetric apparatus, gives only approximate values, which are far less accurate than the results obtained by weighing the copper or cuprous oxid or by Pavy's method. The practising physician, however, who is not familiar with the technic of the more accurate methods, and who desires a method more rapid than the fermentation test, may obtain with this method fairly satisfactory approximate results. By using accurate colorimetric apparatus, the correctness of the values obtained is much greater.

QUANTITATIVE FERMENTATION TESTS FOR GLUCOSE

Upon the addition of yeast, glucose possesses the property of fermentation—i. e., of splitting into alcohol and carbon dioxid. Three tests, based upon three different results of this property, have been devised to determine the quantity of sugar in urine.

Robert's Quantitative Areometric or Densimetric Test.—This is based upon the fact that fermentation considerably diminishes the high specific gravity of sugar-containing urine. From this difference in specific gravity before and after fermentation the percentage of sugar may be determined.

The technic of the test is as follows: The specific gravity of the diabetic urine is estimated in the ordinary way. A piece of compressed yeast (not containing sugar, or, if so, washed out with water) the size of a hazelnut is then added to a definite amount of urine (about 100 cc. are sufficient for testing the specific gravity readily). The mixture is shaken gently, loosely covered with a piece of paper or an inverted beaker, and allowed to remain at the room temperature for twenty-four to thirty-six hours. When fermentation is complete, the yeast will settle to the bottom, the foam will no longer form, and the fluid will become clear above. To be perfectly sure that the fermentation is completed, Trommer's test can be employed. The specific gravity of the completely fermented urine is then determined. If the yeast which has settled to the bottom is stirred up, the urine must first be filtered. If the filtrate is not absolutely bright, a small quantity of magnesia usta is added and the filtration repeated. The urine, which has been

³ To be obtained from Götze, 1

stance, *e. g.*, a solution of glucose, will rotate the plane of the polarization of the ray of light with relation to the analyzing Nicol. Then, to determine again a maximum or minimum of light intensity, the Nicol itself must be rotated through a certain angle. The size of this angle will be proportional to the amount of the interposed substance, *e. g.*, sugar; this amount can, therefore, be calculated from the angle through which it is necessary to rotate the Nicol to produce the maximum or minimum of light. All polariscopes constructed for quantitative analysis depend upon this principle. Their only differences depend upon the employment of various optical contrivances in order to facilitate the determination of the position of the planes of vibrations to each other, *e. g.*, the interposition of doubly refracting bodies, peculiarly ground plates of quartz, etc. They produce peculiar optical appearances, according to the position of the Nicol, colors, stripes, etc.

Wild's instrument uses, as an indicator of the position of the planes of vibration, the system of parallel dark bands which, in a homogeneous polarized light (sodium flame), are made by two crossed quartz plates cut at an angle of 45° to the axis. The advantage of homogeneous light and parallel bands without color, which appear simply dark upon a light background, is that the test depends upon the examiner's sensibility to light alone, and not to color. The test with other instruments, *e. g.*, Soleil-Ventzke's, depends upon the sensibility of the eyes to color. Fig. 243 shows Wild's instrument. The analyzing Nicol prism and the quartz plates are set in the tube *a c*, and the polarizing Nicol prism in the tube *d e*. In looking through the instrument in a dark room, from *a* to the sodium flame at *b*, with the Nicols parallel and crossed, the parallel bands will appear upon the bright background of the field of vision (Fig. 243, IV). If one of the Nicols is rotated 45° by means of the screw *f*, the bands will disappear; further rotation will bring them back.

It should be noted that Pfister and Streit, of Bern, are now supplying Wild's instrument with a number of marked improvements which increase its accuracy, and make it possible, by employing the so-called half-shadow principle, to use a non-homogeneous strong light, and under some circumstances to omit entirely decolorizing the urine.

To estimate the amount of glucose by polarization, 50 cc. of urine are decolorized by shaking with about $\frac{1}{4}$ of this volume of the best animal charcoal and then filtering. If the urine is dark-colored, it must sometimes be allowed to stand for several hours with the animal charcoal, during which time it is frequently shaken; or it may be necessary to boil the urine containing the charcoal for a brief period. The decolorization should be complete. As Späth fears that some of the glucose may be absorbed by the charcoal, he recommends the following method of Patéin and Dufau for decolorization of the urine: A solution of mercuric nitrate is prepared by dissolving 200 gm. of acid nitrate of mercury in 500 to 600 gm. of water, and sodium hydroxid is added until a slight precipitate results. Sufficient water is added to bring the quantity up to 1 liter, and the mixture is filtered. Small quantities of this solution are added to 50 cc. of urine until no further precipitation occurs; a dilute solution of sodium hydroxid is added drop by drop until the reaction of the mixture is neutral or, at most, feebly alkaline; the quantity is brought up to 100 cc. by adding sufficient water, and the mixture is filtered. No precipitate should be produced by the addition of sodium hydroxid to the filtrate.

With urines which are not too deep in color, a Welsbach light may be used and the white light filtered through a glass cell 1 to 2 cm. thick, containing a 4 per cent. solution of potassium bichromate. This is placed between the source of light and the polarizer. In this way the preliminary decolorization may be avoided. With such a source of light the examination may be carried on in daylight, or daylight may be used as the source of light itself.

A metal tube (200 mm. long) (Fig. 243, II), which can be closed at both ends with parallel plain glass disks and metal caps, is filled with the decolorized urine. We must be careful not to include any air-bubbles, and not to press the glass plates by screwing the metal caps too hard, because under pressure the glass becomes doubly refractive, and the dark bands will not disappear with any position of the Nicol. When so arranged, the tube will contain a layer of urine exactly 200 mm. thick. The instrument is adjusted with a sodium flame in a dark room so that the parallel bands absolutely disappear, and the tube which contains the urine is then set upon the rest *c, d*. If the urine contains sugar, the bands will immediately reappear. They are then made to disappear by rotating the polarization plane with the polarizing Nicol by means of the screw *f*. At the moment when they disappear, the size of the angle through which the Nicol prism has been rotated is read off through the telescope *g h*, upon the scale *i*, by means of the vernier *k*. The gas-flame at *l*

serves to illuminate the scale. When the amount of sugar contained is very great, the tube III is substituted for tube II. In the latter, one of the parallel glass disks is placed at *M*, so that the thickness of the urine is *M m*—i. e., 100 mm. The part *M o* is simply an empty continuation of the tube necessary for its adjustment. The angle of rotation is read off and the amount of sugar in tenths of 1 per cent. calculated directly from the following table:

Angle of rotation.	Thickness of urine layer, 100 mm. (length of tube).	Thickness of urine layer, 200 mm. (length of tube).

APPROXIMATE ESTIMATION OF THE AMOUNT OF UREA BY MEANS OF THE SPECIFIC GRAVITY OF THE URINE

Urea affects the specific gravity of urine more than any other constituent; hence the specific gravity of the urine will furnish an approximate measure of the amount of urea, provided, of course, that sugar is absent. Experience has shown that a specific gravity of 1014 corresponds to about 1 per cent. of urea; of 1014 to 1020, to about 1.5 per cent.; of 1020 to 1024, to about 2 and 2.25 per cent.; of 1028, to about 3 per cent. This estimate must be modified in fever and in cachexia, in both of which the chlorid excretion is diminished.

If sugar is present, it must first be removed by fermentation before we can judge of the amount of urea from the specific gravity. In such an event it is better at the same time to employ the areometric method for the estimation of sugar (p. 623 et seq.), and then to recalculate the specific gravity found after fermentation, since the alcohol lowers this to some extent. The degree in which the specific gravity is thus lowered can be best determined by calculating the amount of alcohol from the result of the areometric estimation of sugar. Remembering that approximately equal amounts by weight of alcohol and carbon dioxide are produced in the fermentation of glucose, and having already determined the percentage of glucose, we can easily get the amount of alcohol in the fermented urine, for it will equal about half the amount of sugar found, *e. g.*, after fermentation, approximately a 1.5 per cent. solution of alcohol will result from a diabetic urine containing 3 per cent. of glucose. According to Hirschfeld,¹ the following specific gravities apply to watery solutions of alcohol at 15° C. (water = 1000): 1 per cent., 998.5; 2 per cent., 997; 3 per cent., 995.6; 4 per cent., 994.2. The specific gravity of the urine is thus diminished about 1.5 for every per cent. of alcohol in solution. Therefore, the specific gravity of the fermented urine must be increased by 1.5 for every per cent. of alcohol contained before we can estimate the urea by the above method.

LIEBIG'S METHOD FOR UREA BY TITRATION

Liebig precipitates the urea, in the form of urea mercuric nitrate, by means of a solution of mercuric nitrate. In its original form the method is very simple and convenient, but unless performed very carefully, many errors may arise, and even with the greatest care a number of corrections should be made. On account of these difficulties several modifications have been suggested, all of which furnish better results, but which are more complicated and require more technical skill than the original process. As a matter of fact, moreover, Liebig's method has been abandoned because it does not estimate the amount of urea in the urine, but rather the approximate amount of total nitrogen. (See p. 635.)

KNOP-HÜFNER'S METHOD OF ESTIMATING THE UREA

This is the simplest of all methods. It is to be used for clinical purposes. It depends upon the decomposition of urea into carbon dioxide, water, and nitrogen by means of a solution of sodium hypobromite in an excess of sodium hydroxid. The nitrogen liberated from a definite amount of urine is measured volumetrically, and from this the corresponding amount of urea is calculated. The carbon dioxide is absorbed by the excess of sodium hydroxid. For very accurate analysis the barometer and temperature must be considered. Other nitrogenous constituents of the urine (uric acid, kreatinin, etc.), and especially ammonia, are partially broken up at the same time, liberating nitrogen: hence the method is not absolutely accurate. According to Emerson, about 8 per cent. of the urea is not changed to carbon dioxide and nitrogen. Hence, one obtains a compensating error. Both are not large. If a diabetic urine be examined, a relatively large error may be encountered, owing to the presence of much ammonia. This may be avoided by making the urine alkaline with sodium hydroxid, and removing the free ammonia with a current of air. Proteins evolve nitrogen with sodium hypobromite. They should be removed before the estimation is performed.

Fig. 247.—Höfner's apparatus for estimation of the urea.

¹ [The method of preparation of can be highly recommended. Two s any ordinary length of time:

1. A solution of 125 gm. of brom water to make the volume up to 100

2. A solution of sodium hydroxi To prepare the hypobromite for use dilute with $1\frac{1}{2}$ volumes of water.—E

minutes to one-half hour. The bubbles adhering to the sides of the vessel are then gently shaken into the eudiometer tube, which is closed under the level of the salt solution with the thumb. It is then removed, and submerged as completely as possible, opened downward, in a large cylinder filled with water at the room temperature. After about fifteen minutes the eudiometer tube and its contents will be at the same temperature as the surrounding water. The tube is then lifted far enough out of the water to equalize the levels of the fluid inside and outside, and at this moment the volume of the inclosed nitrogen is read off. The temperature of the water and the barometric pressure should also be recorded. The volume of gas estimated must now, for the purpose of calculation, be reduced to 0° C., 760 mm. barometric pressure, and absolute dryness, according to the formula:

$$v^1 = \frac{v(b-w)}{760(1+0.00366t)}$$

v^1 = Reduced volume desired.

v = Volume read off.

b = Barometric pressure at the time of reading, in mm. Hg.

w = Tension of water vapor at a temperature t , in mm. Hg.

t = Temperature of water at time of reading.

0.00366 = Coefficient of expansion of gases for 1° C.

The values for w corresponding to the temperatures usually met with are as follows:

10° C.....	9.126	18° C.....	15.351
11° C.....	9.751	19° C.....	16.345
12° C.....	10.421	20° C.....	17.396
13° C.....	11.130	21° C.....	18.505
14° C.....	11.882	22° C.....	19.675
15° C.....	12.677	23° C.....	20.909
16° C.....	13.519	24° C.....	22.211
17° C.....	14.009	25° C.....	23.582

One gm. of urea furnishes 354.3 cc. of nitrogen (a little less than the theoretic quantity); hence, the following proportion will determine the amount of urea (x) in the 5 cc. of urine employed.

$$\begin{array}{rcl} 354.3: 1 & = & v': x \\ x & = & \frac{v'}{354.3} \text{ gm.} \end{array}$$

The percentage of urea contained in the urine can be very easily determined by multiplying this number by 20. Of course, if the urine was diluted before the estimation, this dilution must also be considered.

The author considers that Gerrard's¹ improvement upon Hüfner's apparatus has been shown to be the most practical for the practitioner (Fig. 248).

A graduated glass tube, a , fixed in a wooden stand, is connected at the lower end by means of a side projection and a rubber tube with a vessel, b , which is open at the top, and at its upper end with a wide-necked bottle, d , by means of a perforated rubber stopper, c , and a rubber tube. Vessel b may be raised or lowered upon the graduated tube by the metal spring clamp e . The wide-necked bottle, d , is filled with 100 cc. of sodium hypobromite solution; 5 cc. of urine are poured into the small test-tube, f , which is carefully placed in bottle d , so as to be, for the time being, protected from the hypobromite solution. The bottle is then connected with the rest of the apparatus by means of the perforated rubber stopper g and tube gh . Next, the stopper c is removed and vessel a is filled with water up to the zero mark of the scale. Of course, the communicating vessel b , which has been pushed up toward the top, also fills to the same level. The stopper c is now replaced. While this is being done, the spring clamp i , which closes the rubber tube attached to the glass tube h , is opened carefully so that at the moment of replacing c there will be no increase of pressure of the air upon the level of the water. The fluid, therefore, remains at the same level in the communicating vessels a and b . The spring clamp i is now very carefully closed again. After the apparatus has been connected in this fashion, the urine in the little glass f is easily

¹ Lancet, 1884, ii, p. 952.

ate to them, so that the formula then becomes, when h and b represent the amounts of urea corresponding to the barometric pressures,

$$\frac{h}{h'} = \frac{b}{b'}.$$

It is advisable to control the empirical scale by adding a scale in cubic centimeters on tube a . Then the calculation for any temperature or barometric pressure can be made in the same manner as with Hüfner's apparatus. (See p. 630.) The same rules for dilution, of course, apply for this apparatus as for Hüfner's.

Not only is Gerrard's instrument more compact than Hüfner's, but the gas can be entirely evolved within a few moments by shaking bottle d .

The weak point of the apparatus is the closure of the upper end by a stop-cock, which may easily allow of the escape of gas, and consequently give rise to an erroneous result. Dupré's modification of Hüfner's apparatus (Fig. 289) can be thoroughly recommended, and is the one which is employed in the author's clinic. The illustration should be sufficient without further description. It differs from Gerrard's apparatus in that the reduction of the gas to atmospheric pressure is accomplished by moving the buret in which the gas collects, and which is suspended in a cylinder filled with water. In this instrument the stop-cock at the upper end of the buret should be carefully tested, in order to avoid losing any of the gas.

Table giving the amount of urea in grams for each cc. of nitrogen evolved in the Knop-Hüfner method.

According to Seiler and Ratschy (Schweiz. Woch. Pharmacie, 1889, No. 46) the intermediate values for temperature between these given in the table may be interpolated. They are given in full in the original table of Seiler and Ratschy:

ESTIMATION OF UREA BY SCHÖNDORFF'S METHOD

The principle of this method is as follows: The urine is precipitated by phosphotungstic acid containing hydrochloric acid, during which the urea remains in solution. The filtrate is then heated with phosphoric acid, ammonium phosphate is formed, and the ammonia is freed from this compound by the addition of caustic soda. The ammonia is then removed by distillation and determined by titration, as in Kjeldahl's method (see below).

As the opinions in reference to the value of this method are still very contradictory,¹ it will suffice to refer the reader to the original work of Schöndorff (Pflüger's Arch., vol. lxii); to v. Jaksch (Klin. Diagnostik innerer Krankheiten, fifth ed.); to Pfäundler (Zeit. f. physiol. Chemie, 1900, vol. xxx), and to Folin (ibid., 1901, vol. xxxii).

also be estimated, the total ammonia found can be done by the method.

[Methods for Determining Urea.—

which has been used by the clinician for some modification of the hypobromite test by those engaged in a more accurate study in any of its most varied forms is entirely the purpose. It still occupies a prominent place in chemistry. The reason that it fails to give accurate results in the estimation of the urea in the urine is a fundamental one, and not of apparatus. Urea is not completely decomposed by hypobromite in the concentrations occurring in the urine, and substances constantly occurring in this fluid and substances entering into the group are partly decomposed. The reason why the results agree with the more accurate methods is that the errors may compensate one another.

Only two methods at the present time are used for the accurate estimation of the urea nitrogen, the Morner-Sjöqvist and of Folin. The latter is more and more entering into clinical laboratories, and this method, or some modification of it, will be adopted for general clinical use.

¹ Zeit. f. physiol. Chem., xxxii, p. 505

ESTIMATION OF THE AMOUNT OF TOTAL NITROGEN IN THE URINE BY KJELDAHL'S METHOD

Approximate values for the amount of total nitrogen in the urine may be obtained from the estimation of the amount of urea (Knop-Hüfner's method).¹ In the calculation we must assume that 15 parts of urea contain 7 parts of nitrogen, and in this calculate the amount of nitrogen belonging to the urea present. This amount must then be multiplied empirically for normal urine by 1.136, and for fever urine by 1.18. This will approximately furnish the amount of total nitrogen excreted.

Liebig's method, the so-called urea titration, also approximately estimates the amount of total nitrogen. The figures found for the quantity of urea by this method are too high, so that, in fact, the nitrogen obtained from the calculation of the urea supposed to be present really corresponds approximately to the total nitrogen contained in the urine.

For a perfectly exact estimation of the amount of total nitrogen in the urine, Kjeldahl's method is to-day almost exclusively employed. The principle of the method is that the organic constituents of the urine are destroyed by oxidation when the urine is heated with concentrated sulphuric acid, and that the nitrogen of those substances which do not contain it combined with oxygen appears as ammonium sulphate. The urea is changed directly into carbon dioxide and ammonia. The nitrogen is estimated by liberating the ammonia from the acid solution with potassium or sodium hydroxid, distilling it off, and passing it into a measured amount of acid. The acid remaining is then titrated with an alkali.

The details of the method, including certain modifications recommended by Wilfahrt and by Salkowski, are as follows: The acid used for oxidizing purposes is a mixture of 500 cc. of concentrated sulphuric acid and 100 gm. of phosphoric anhydrid. Pure sulphuric acid may be employed, but oxidation takes longer. It is also necessary to have a $\frac{N}{2}$ hydrochloric acid solution prepared by diluting the normal acid with an equal amount of water. A $\frac{N}{2}$ solution of sodium hydroxid is also essential.

Ten cc. of urine (or 5 cc. of concentrated) are put into a Kjeldahl flask with round bottom and long neck, to which are added 10 cc. of the sulphuric acid mixture, after about 0.4 gm. of finely divided mercuric oxid² has just been placed in the flask. This mercury acts catalytically in aiding oxidation. The flask is next loosely closed with a glass ball, and heated in a fume closet while kept somewhat tilted. The flame should not be too high and should be applied until the solution is colorless. Even the slightest tinge of yellow suggests that oxidation is not complete unless iron compounds are present in rather large quantities. As a rule, it takes at the most three hours to complete the oxidation. The mixture is now allowed to cool, and is poured into a distilling flask by means of a funnel. The digestion-flask and the round glass stopper are rinsed with 100 cc. of water, which is added to the contents of the distillation-flask. Next, 40 cc. of sodium hydroxid solution of specific gravity 1.340 are added and (in order to precipitate the mercury, which otherwise would form amido-compounds with the ammonia) this is followed by 25 cc. of potassium sulphid solution (40 gm. to the liter). The flask is now *quickly* connected with the distilling tube. This tube passes through a condenser, and the end is placed in an Erlenmeyer flask of about 200 to 300 cc. capacity. This latter vessel contains 20 cc. of the $\frac{N}{2}$ hydrochloric acid, and just enough water to keep the end of the condenser tube submerged.

Distillation is continued until no more ammonia escapes and the distilled steam no longer develops ammonium chlorid fumes, when a glass rod, moistened with HCl, is held in front of the open end. This condition of affairs usually obtains when about 100 cc. of fluid have been obtained by distillation. Several drops of a methyl-orange or cyanin solution³ are now added to the $\frac{N}{2}$ hydrochloric acid solution to act as indicator, and the amount of contained ammonia is determined by titration

¹ Cf. Anleitung zur qualitativen und quantitativen Harnanalyse, Neubauer und Vogel, Neubearbeitet von H. Huppert, 1890, p. 531.

² Instead of using mercuric oxid as a catalyzer, copper sulphate may be employed. The subsequent precipitation with potassium sulphid is avoided. The digestion is finished when the solution assumes a light greenish-blue color.

³ Cochineal solution, prepared by extracting ground cochineal with 50 per cent. alcohol, is often employed. The indicator can be used with artificial light.

The technic for the procedure is as follows: After the oxidation of 5 to 10 cc. of urine, according to the method given above: Instead of using mercuric oxid or copper sulphate, Denigès employs 5 cc. of a 30 per cent. neutral potassium oxalate as a catalyzing agent. The former compounds combine with the ammonia. The solution is diluted with a little water, and partially neutralized with potassium or sodium hydroxid until the reaction is only faintly acid, and then the volume made up to 50 cc. For azometric analysis we use 20 cc. (corresponding to 2 or 4 cc. of urine) of this solution and treat it exactly like the urine in Knop-Hüfner's method (p. 629), although, of course, the size of the apparatus must be changed somewhat. With Gerrard's or Dupré's modification this can be accomplished very simply by selecting a tube (Figs. 248 and 249) which will contain 20 cc. instead of 5 cc.

The total elimination of nitrogen in the urine generally runs parallel to the urea excretion, which, of course, contains the greater share of the nitrogen. In acute yellow atrophy of the liver, however, the comparison of the total amounts of nitrogen and of urea elimination shows a strikingly different result. In this disease the major portion of nitrogen is eliminated as leucin and tyrosin, and little or no urea is excreted in the urine. In diabetic acidosis a large amount of the nitrogen may be excreted in the form of ammonia.

QUANTITATIVE ESTIMATION OF URIC ACID

A healthy adult excretes 0.2 to 1 gm. of uric acid in the urine during the course of twenty-four hours. The amount increases physiologically with increased ingestion of food, and pathologically with increased metabolism of nitrogen in about the same proportion as urea. The amount of uric acid in normal urine varies with its specific gravity. The last two numbers of the specific gravity (calculated to 4 places) multiplied by 2 gives approximately the number of centigrams of uric acid in the liter. The daily excretion of uric acid is pathologically increased in fever, in leukemia, and in cirrhosis of the liver. Opinions still differ about uric-acid excretion before, during, and after attacks of gout. Recent investigations probably disprove the old theory—that in gout more uric acid is permanently produced than normally (so-called uric-acid diathesis). According to Haig, the amount of uric acid formed in the body bears a constant ratio to the amount of urea (1 : 35 both under physiologic and under pathologic conditions—*e. g.*, even in gout). He claims that variations in this ratio are due chiefly to irregularities of elimination. This seems to be not altogether proved. Again, the elimination of uric acid will be increased, *ceteris paribus*, by the ingestion of uric acid and other xanthin bodies, as well as by food substances rich in nuclein (rich in cell nuclei).

According to Grübler,¹ the amount of uric acid in the urine may be approximately estimated by stratifying upon a layer of nitric acid a specimen of urine in a test-tube, so that the volume of urine shall be to the volume of acid as 3 : 2. After a short interval uric acid will precipitate out as a cloudy ring at the junction of the two fluids. If the amount of uric acid is increased, the precipitation will be plain within five minutes; if diminished, not until later. Of course, this test applies only when the daily volume of urine is normal. If the volume is diminished, the urine must be diluted up to the normal amount with water. Albuminous urine must first be freed from protein by boiling, after slight acidification.

Heintz's quantitative method of estimating the amount of uric acid has been abandoned entirely. It is not trustworthy. The following three methods are, however, quite accurate:

¹ Laquer, Schmidt's Jahrbücher, 1892, vol. cexxxvi, No. 10, p. 78.

THE LUDWIG-SALKOWSKI METHOD OF ESTIMATING URIC ACID

This method gives the most accurate results. The principle is as follows:

Uric acid, even if present only as a trace, is precipitated as silver urate upon the addition of a mixture of silver nitrate and of ammoniacal magnesia solution, an alkaline sulphid solution and so decomposed. The urate will be formed; the latter is filtered off. The solution upon evaporation with hydrochloric acid

The precipitation of uric acid by the addition has, aside from the advantage of the slight precipitation of urate, the additional advantage that at the same time mixing with the otherwise gelatinous precipitate is more easy to be washed.

For the procedure, the following solutions are

1. Ammoniacal silver solution: 26 gm. of silver nitrate, and enough ammonia added to the solution to dissolve the silver oxid. The mixture is then diluted with water.

2. Ammoniacal magnesia solution: 100 gm. of magnesia in water. About 200 cc. of a cold saturated ammonium hydroxid solution and then enough concentrated ammonium hydroxid to give an ammoniacal odor. This mixture contains a dose of ammonium chlorid, which is not precipitable by silver nitrate with water up to 1 liter.

The solutions as given in Ludwig's directions 10 cc. will suffice for 100 cc. of urine.

Ten cc.¹ of the silver solution are mixed with ten cc. of the ammoniacal magnesia solution and the resulting precipitate of silver chlorid is filtered off. The precipitate does not dissolve in ammonium hydroxid, which can be dissolved by adding a clear solution is poured, with stirring, into a beaker. The precipitate which forms is allowed to settle a little, and washed two or three times with water. No wash-water have been added. Any of the precipitate remains on the filter with wash-water. Traces of the precipitate to remain in the beaker, because all the precipitate is removed by the aid of a glass rod, to the beaker again, after which the filter-paper must be kept intact.

The precipitate is now placed in about 200 cc. of water and acidulated with hydrochloric acid, and the mixture is filtered. Shaffer and Folin recommend the previous addition of a solution of cupric sulphate, after which the filtrate is acidulated with hydrochloric acid. After the saturation with hydrogen sulphid, the solution is allowed to stand for ten minutes, and the hot solution of uric acid is then added. The precipitate should be thoroughly washed with water and throws down no silver sulphid upon the addition of ammonium sulphid. The method, in which the silver is removed by an alkaline solution, is now placed in a porcelain dish upon a water-bath. From 5 to 10 drops of hydrochloric acid are now added. The solution is allowed to stand for twelve hours, and the uric-acid crystals are filtered off on a filter which has been dried at 110° C. The crystals are washed with a small quantity of water until they are free from silver. The filtrate, together with that of the wash-water, is evaporated to dryness, and the crystals are again washed twice with absolute alcohol and weighed.

Any sediment of urates must be dissolved in water. Any precipitated uric acid can be dissolved in water as possible and the solution then mixed with the filtrate. The filtrate should not be used, for it would cause excessive loss of uric acid. It would not allow any phosphate to remain for the

¹ The following description is partly quoted from *Qualitative und quantitative Harnanalyse von Huppert*, 1890.

sediment with the silver magnesium precipitation. Adding sodium phosphate to the urine before the silver precipitation would, however, prevent this difficulty.

Stadthagen claims that peptones and proteoses do not influence the uric acid precipitation, but the urine must first be freed from albumin.

THE HOPKINS-WÖRNER METHOD OF URIC-ACID ESTIMATION¹

This method is, according to all observers, simple and perfectly accurate. It depends upon the following principle: Ammonium chlorid precipitates uric acid quantitatively from the urine as ammonium urate. The determination is carried out as follows: 150 cc. of urine are warmed in a beaker to 40° to 45° C., and 30 gm. of ammonium chlorid allowed to dissolve in it. The precipitate of ammonium urate which results after one-half to one hour's standing is filtered off, and washed free from chlorin with a 10 per cent. solution of ammonium sulphate. It is then dissolved upon the filter by a warm 1 to 2 per cent. solution of sodium hydroxid, the filter washed afterward with hot water, and the filtrate and wash-water, collected in a porcelain dish, heated upon a water-bath long enough to drive off all the ammonia. The alkaline solution of uric acid is then decomposed with 15 cc. of concentrated sulphuric acid and some copper sulphate.² After adding sodium hydroxid, the free ammonia is estimated in the usual manner. Such a small amount of ammonia is more accurately measured by employing a $\frac{N}{10}$ oxalic acid instead of a $\frac{N}{2}$, as is usual, and also by retitration. One cc. $\frac{N}{10}$ oxalic acid corresponds to 0.0042 gm. of uric acid. Strongly acid urines under some conditions prevent the precipitation of ammonium urate, or make such a precipitation incomplete; hence, Levandowski³ recommends that the urine be neutralized before the precipitation. If performed in this way, the method should be very exact and trustworthy.

KOWARSKI'S MODIFICATION OF HOPKINS' METHOD

A. Kowarski has modified the above method for clinical purposes.⁴ Ten cc. of urine are measured out accurately into a centrifuge tube holding 15 cc. Two or 3 drops of ammonium hydroxid solution and 3 gm. of powdered ammonium chlorid are added. The tube is closed with a rubber stopper and shaken until the ammonium chlorid is dissolved. Ammonium urate is precipitated in the form of a flocculent sediment. The phosphates which are precipitated at the same time do not interfere with the estimation. The tube is allowed to stand for two hours. The mixture is then centrifuged for one to two minutes. The supernatant clear liquid can be poured off from the sediment without loss. This should be done at one time, as much shaking of the tube will disturb the sediment.

To the sediment 5 drops of concentrated hydrochloric acid are added, and the whole heated carefully over a small flame. The ammonium urate is dissolved, and the uric acid commences to separate out in the form of a crystalline precipitate. The separation is complete in one hour. Two cc. of water are added to the precipitate, the whole shaken, and again centrifuged. Ten revolutions of the centrifuge are sufficient completely to sediment the precipitate. The supernatant fluid is again poured off, and the precipitate washed at least three times with 2 cc. of alcohol, until the washings are neutral to litmus. The washing takes at the most three to five minutes. To the sediment are then added 2 cc. of hot water, 1 drop of phenolphthalein, and the mixture titrated with $\frac{N}{10}$ piperidin solution⁵ prepared as given below. The titration is carried on until a permanent pink is obtained. The solution must be constantly shaken during the titration. If the number of cubic centimeters of piperidin solution used be multiplied by 3.36, one obtains the number of milligrams of uric acid contained in 10 cc. of urine. The piperidin solution is permanent. It can be controlled from time to time by titration against a standard solution of sulphuric acid. The piperidin solution is prepared⁶ by dissolving more

Ebstein, and Horbaczewski. The chemistry of these compounds is mainly due to the most important researches of Emil Fischer. These authors have shown the clinical importance of these bases. According to our present knowledge, their formation depends upon the destruction of cellular elements, especially of the cell nuclei rich in nuclein. The following scheme may help the reader to understand the derivation of the purin bodies more clearly:

The purin compounds which occur in the urine are: Xanthin, guanin, hypoxanthin, adenin, heteroxanthin, paraxanthin, episarkin, epiguanin, methylxanthin, carnin. Heteroxanthin, paraxanthin, and methylxanthin are formed principally from the caffein, theobromin, and theophyllin of the food. The presence of guanin and carnin in the urine has not been made out with perfect certainty. The amounts of purin bases which are excreted in the twenty-four hours vary greatly. According to Emerson, 15.6 to 45.7 mg. are eliminated, while Camerer places the amount on a mixed diet at 87, on vegetable diet at 111, and on a meat diet at 44 mg. Concerning the pathologic significance of these compounds, but little is known, except that xanthin, hypoxanthin, and adenin are increased in leukemia, and that guanin is also found in this disease. Tuberculosis also appears to be associated with an increase in the purin bases. There also appears to be a certain antagonism between uric acid and the purin bases. When the latter are increased, the uric acid is excreted in lessened amount. Regarding the connection between the purin bases and the diazo-reaction, see p. 607.

Until lately, Kruger and Wulff's¹ method has been generally used to estimate the total amount of the purin bodies. But it has been proved inaccurate, and so will not be described.

Salkowski's method is exact. It depends upon the precipitation of the purin bases by an ammoniacal silver solution. It determines the purin bases alone, and is analogous to the Ludwig-Salkowski method for estimating uric acid. Denigès' method is employed at the Bern Clinic quite successfully, and will also be described.

SALKOWSKI'S METHOD OF ESTIMATING THE PURIN BASES²

The precipitate obtained from the urine (at least 500 to 1000 cc.), by precipitating with the silver magnesia solution, is, after carefully washing, decomposed by hydrogen sulphid (just as in the Ludwig-Salkowski uric acid method, p. 638 et seq.). The filtrate is evaporated to dryness, and the residue extracted with 2 to 3 per cent. sulphuric acid. The latter dissolves the purin bases and leaves the uric acid undissolved. To be absolutely sure that at the most only traces of uric acid become dissolved, Salkowski delays filtering until the following day. The filtrate is now rendered alkaline with ammonia, and precipitated again with the silver solution. The amount of silver present in the precipitate is determined (after washing) by titration with ammonium thiocyanate. From the amount of silver present in the precipitate can be calculated the quantity of xanthin or purin bases present. One cc. of $\frac{1}{10}$ ammonium thiocyanate corresponds to 0.00152 gm. xanthin.

The amount of xanthin is either figured out or the xanthin bases are separated directly from the second silver precipitate and weighed.

METHOD FOR THE DETERMINATION OF URIC ACID, ACCORDING TO SALKOWSKI

This method is based on the fact that uric acid is precipitated quantitatively by an ammoniacal solution of magnesium chlorid, and that a precipitate is produced by silver nitrate in an ammoniacal solution of potassium iodid only after all potassium cyanid has been added. This test furnishes the quantity of purin bases in the urine.

The following solutions are necessary:

1. A $\frac{N}{20}$ ammoniacal silver magnesium solution. 150 gm. of pure ammonium chlorid are placed in a 300-cc. bottle; it is then filled three-quarters full with water, and is gently heated on the water-bath until the solid and liquid are mixed with 500 cc. of a

2. A $\frac{N}{10}$ solution of potassium cyanid. 10 gm. of potassium cyanid are dissolved in 1 liter of water, to which are added 10 cc. of ammonia, then filtered. This solution is too concentrated for the precipitation of silver that 10 cc. of the latter cyanid solution, since 2 molecules of silver are precipitated by 1 molecule of cyanid. (Formation of potassium silver cyanid.) 20 cc. of the potassium cyanid solution 20 cc. are placed in a 100-cc. bottle, and a few drops of potassium ammonia, and a sufficient quantity of the $\frac{N}{10}$ silver solution so as to produce a persistent cloudiness. If we assume that n cc. of the silver solution, then there is n cc. of the silver solution in the proportion 2 n cc. to 100 cc. of water. The solution so prepared will correspond to an equivalent of 0.0168 gm. of uric acid.

3. A solution of potassium iodid prepared by dissolving 10 gm. in 100 cc. of water and adding 2 cc. of ammonia.

4. A $\frac{N}{10}$ silver solution. Seventeen gm. of silver nitrate dissolved in 1 liter of water.

These solutions are utilized in the following manner: To 100 cc. of urine is added 10 cc. of the $\frac{N}{20}$ silver magnesium solution. This solution is then filtered, and the filtrate, which corresponds to 80 cc. of the original urine, is added 20 cc. of the potassium cyanid solution. This solution would react exactly with 20 cc. of the silver solution had not been used up by the purin bases in the urine. Inasmuch as the quantity of silver is known, the excess of silver cyanid. This excess is estimated by a solution of potassium iodid solution, and then, from a solution of silver nitrate, a cloudiness is produced. The amount of silver nitrate added exactly to the amount of silver held in the filtrate. The greater part of the purin precipitates as a result, so far as uric acid is concerned, and the remainder is precipitated as potassium urate.

Each cubic centimeter of the $\frac{N}{10}$ silver solution corresponds to 0.0168 gm. of uric acid. If n cc. silver solution have been used, then the amount of uric acid is $n \times 0.0168$ and 1 liter of urine contains $\frac{0}{1000} \times n \times 0.0168$ gm. of uric acid.

QUANTITATIVE ESTIMATION

This estimation may have a certain value in the breaking down of tissue. (See Oswald's *Chemie der organischen Verbindungen* of Salkowski² and Autenrieth and Baur³.)

¹ After C. Vieillard, *L'urine humaine*, pharm. de Bordeaux, 1884, p. 137.

² *Zeit. f. physiol. Chemie*, 1900, vol. 2, p. 137.

QUANTITATIVE ESTIMATION OF INDICAN

An approximate idea of the amount of indican in the urine may be had from the depth of color produced in the qualitative tests for this substance.

There are a number of methods which have been suggested for the quantitative estimation of indican, some of which are based on colorimetric principles, others which are based on titration. Most of these methods are too complicated for clinical purposes. One of the most convenient is that of Strauss.¹ The urine is oxidized with a reagent and the indigo formed is extracted with chloroform. The color of the chloroform is compared with a standard solution. Strauss uses for the extraction the separating funnel figured on p. 451. The funnel must be graduated in 5 cc. As a standard solution for comparison, Strauss employs a solution of 1 mg. of indigotin (Kahlbaum) in 1000 cc. of chloroform. Strauss' method is as follows: Twenty cc. of the urine are precipitated with 5 cc. of a 20 per cent. basic lead acetate solution. After filtering, 10 cc. of the filtrate are introduced into the separatory funnel and 10 cc. of Obermeyer's reagent (see p. 580) added. Five cc. of chloroform are now added, and the contents of the funnel shaken. It is then allowed to stand for two to three minutes. The liquid is extracted several times with chloroform until the reagent extracts no more of the indigo. The chloroform is then placed in a graduated cylinder, and diluted with pure chloroform until the color is equal to that of the standard solution of indigotin. With urines containing much indican the extraction must be repeated four or five times. The indigo solution must be placed in a test-tube of the same diameter as that of the indican solution. Both should be held in front of a white paper. If the total volume of the chloroform solution used for the extraction be 1 cc., and the amount of chloroform which was necessary to dilute the solution until it reached the tint of the comparison solution y , we obtain the volume x , to which the whole extract must be brought to give the requisite depth of color.

$$x = a \frac{y}{2} \left(\text{as } \frac{x}{a} = \frac{y}{2} \right).$$

This calculated volume of chloroform, to which the total chloroform extract must be brought is proportional to the amount of indigo extracted. Strauss found variations of the chloroform value from 5 to 10 cc. (normal) to 15 cc. in tuberculous peritonitis, chronic catarrh of the small intestines, and purulent peritonitis. More or less marked variations were found by the same observer in pulmonary tuberculosis, gastric carcinoma, pneumonia, acute rheumatic arthritis, acute endocarditis, typhoid, and acute perityphlitis.

As the standard indigotin solution contains 1 mg. in 1 liter, the amount of indican can be easily calculated. As the amount of urine used is only 8 cc. (10 cc. of urine + 5 cc. of basic lead acetate solution, and of this 10 cc. of the filtrate), the results must be calculated on this basis. Strauss estimates the amount of indican eliminated by a healthy person in terms of indigotin at 2 to 4 mg. in the twenty-four hours. With urines containing much indican, the amount may rise to 60 mg. and more. The method takes fifteen to twenty minutes.

The test solutions must be kept in the dark, and even then must be renewed from time to time. The author recommends that a more concentrated solution be prepared. This is more stable, and from this the requisite dilution may be made easily.

ESTIMATION OF THE KREATININ IN THE URINE

Kreatinin in the urine is probably derived from the kreatin of the muscles. Kreatinin is the anhydrid of kreatin. Normal urine probably does not contain kreatin. The excretion of kreatinin generally runs parallel to the excretion of urea. An increased ingestion of meat, and in all probability any augmentation of muscular metabolism, increases the excretion of kreatinin. Here lies the clinical interest in the quantity of kreatinin in the urine. The various results of experiment as to whether the kreatinin increases in amount with increased muscular work differ. It is generally assumed that the excretion of kreatinin is not increased by muscular exertion. According to Thomas and Späth,² the daily excretion of kreatinin of healthy men is about 1 gm. The excretion of kreatinin in disease

¹ Deut. med. Woch., 1902, No. 16, p. 299.

² Harnanalyse von Neubauer und Vogel, Neubearbeitet von Huppert und Thoma, Kriedel, Wiesbaden, 1890.

(in spite of its theoretic interest) has not been observed. A pronounced increase has as yet been reported in only a few cases.

Kreatinin behaves like uric acid in that it does not interfere with Trommer's test for glucose. It does not reduce bismuth.

An accurate quantitative determination of kreatinin requires preparing and weighing the kreatinin. Salkowski² has modified the Neubauer method and substituted for the technic. (Compare Neubauer's method.)

Kreatinin can be demonstrated qualitatively by the following two simple methods, which may be used for the purpose.

Jaffe's Reaction.⁴—The addition of a few drops of a 1% solution of sodium picramic acid and a few drops of diluted sodium or potassium hydroxide to a urine containing kreatinin will immediately produce an intense brown color. If kreatinin in the urine is only 1:5000. The color will then persist unchanged for hours. If the color is a much less intense one; hence, it is wise to test for kreatinin that may be present in the urine. Folin's method of estimation of kreatinin (see Supplement).

Th. Weil's Reaction.⁵—A few drops of a 1% solution of potassium ferricyanide are added to the urine, and then so much of a 1% solution of picric acid is present, a ruby-red color will result. At this point the reaction is identical with that of uric acid; however, acetone is present, the fluid turns blue; this is not the case with kreatinin. So the addition of acetic acid and subsequent boiling will produce a bluish coloration (Prussian blue). Before the addition of acetic acid be expelled by boiling the urine.

THE QUANTITATIVE ESTIMATION OF KREATININ IN URINE, ACCORDING TO THE METHOD OF GOTTLIEB

The researches of Gottlieb and his associates show that kreatin and kreatinin play an important role in the metabolism and not, as was formerly assumed, a negligible one. Accordingly, it is quite possible that the amount of kreatinin in the urine will in the future become of some importance. Therefore, briefly notice the method of estimation of kreatinin in the urine. The older method, proposed by Gottlieb, is quite complicated, and Gottlieb and his associates have introduced the use of a modified procedure introduced by Folin.

The Estimation of Kreatinin.—Folin's method depends upon a modification of Jaffe's reaction. It enables quantitative results to be obtained. The method of estimation of kreatinin to Picramic Acid with the use of Picric Acid in an Alkaline Dubosq colorimeter with two tubes. One tube is filled with a fluid consisting of a normal solution of sodium picramic acid; the other is filled with urine in which kreatinin is to be estimated by the method of Jaffé. The instrument is used to set the level of fluids within 1 to 2 mm. on a scale when, by transmitted light, the color of the two fluids is compared.

¹ Ann. d. Chemie. u. Pharm., 1861, vol. xxi, p. 112, and Zeit. f. physiol. Chemie, 1886, x, 112.

⁵ Th. Weil, Ber. d. chem. Gesellschaft, 1886, xix, 112.

⁶ Zeit. f. physiol. Chemie, Bd. lli, and llii.

approaches the other most closely. From these figures the kreatinin content may be calculated by the use of colorimetric principles, if the color value of the standard fluid used for comparison has been estimated. For making the estimation one tube is filled with standard fluid up to the mark 8 mm. Then 10 to 20 cc. of urine (the exact quantity needed is determined by repeating the test) are placed in a flask with a mark at 500 cc., and to these are added 15 cc. of a 12 per cent. solution of picric acid and 5 cc. of 10 per cent. solution of sodium hydroxid. After ten minutes the color reaction assumes its maximum; then the mixture is diluted with water until the total volume equals 500 cc., and a portion of it is placed in the second tube of the colorimeter, which is then adjusted so that the colors of the fluids in the tubes approximate each other. The color of the standard fluid corresponds to 0.01 kreatinin in 500 cc., and the amount in the urine tested can, therefore, be easily estimated from the figures obtained. Gottlieb and Stangassinger have retained the principle of Folin's method, but have constructed a simpler and a cheaper colorimeter which is manufactured by Runne in Heidelberg; in this instrument the prisms of the original colorimeter are replaced by plane mirrors. A cut of the apparatus appears in the paper in Vol. lii of the *Zeit. f. physiol. Chemie*, quoted above. From their researches they concluded that this method of estimating kreatinin by comparing with a standard solution of dichromate of potassium gives exact results when the level of the kreatinin solutions ranges from 4.2 to 14 mm.; they, therefore, always attempt to bring the levels of the fluid between these ranges before the reading is made, if there is sufficient material for the purpose. If the material on hand allows of one estimation only and the approximate kreatinin content of it is unknown, they make use of a table constructed experimentally by measuring standard kreatinin solutions in the apparatus. This table gives the amounts of the solution of kreatinin containing 1.5, 14, and 20 mg. in 500 cc. that would correspond in color to that of 8 mm. of the standard solution of the dichromate in the colorimeter. Any intervening values may be easily interpolated in this table. According to Dreiholz,¹ the presence of sugar in the urine does not interfere with the accuracy of the test.

The Estimation of Kreatin.—The statement made on p. 643 of this book that normal urine contains kreatinin, but probably no kreatin, must be corrected, because of the results obtained by Folin and Klercker since the statement has been made. They have shown that kreatin does appear in the normal urine, and it is, therefore, possible that estimation of this body in the urine may likewise assume some importance in the future. The attempt has been made to apply Folin's method to the estimation of kreatin.

[**The Nitrogen Partition.**—Recently in America and England a more detailed scheme of analysis of the urine has been employed for the purposes of diagnosis. It has been used to determine whether the organs concerned in the elaboration of the end-products of metabolism are at fault.

Such a scheme of analysis involves the determination of total nitrogen, ammonia nitrogen, urea nitrogen, kreatin and kreatinin nitrogen, and uric acid nitrogen. These latter amounts are added together and

¹ Dreiholz, *Zur Frage der Kreatininausscheidung im Harn*, Inaugural Dissertation, Greifswald, 1908.

URINARY

m subtracted from the total is called the undetermined. Some investigators have determined nitrogen alone, others have examined the whole in an attempt to use the whole in an attempt to use the whole.

The conditions to which the method is particularly applied are the toxic conditions.

The way in which the analyses of normal individuals which have been used as standards for comparison are difficult in the interpretation.

One chief difficulty lies in the fact that the amount of nitrogen examined has not been sufficient. A normal urine may vary. Patients suffering from typhoid fever and of undernutrition. They find it is quite insufficient for the purpose of nutrition has by itself, and in a logic condition, a profound amount of information which is not sufficient of the nitrogen in cases is very scanty, so that a comparison with which to compare pathological conditions. While the method of determination of the nitrogen is not perfect, lack of data, it is believed that it may perform a useful discussion.¹—C. G. L. W.]

QUANTITATIVE ESTIMATION OF

The amount of chlorides eliminated in twenty-four hours varies between 10 and 20 grams. Chlorides of the urine are not eliminated in the formation of exudates and in fever.

It has been assumed that the amount of chloride in the urine in fever depends entirely on the amount of chloride ingested.

This is certainly wrong, because if food is ingested, no such marked increase in the amount of chloride in the urine, as, for example, in patients with typhoid fever, is observed. It is of chlorin eliminated increases without any increased intake of chlorin. The diminution of chlorin in the urine is a theory suggests that in fever the chlorin, are disintegrated into proteins. Another theory suggests that the urine is deprived of a certain amount of chlorin.

A recent discussion of the value of the method of estimation of chlorides in the urine, *Amer. Jour. Med. Sci.*, 1906, c. 1, 100; *Int. Med.*, 1909, iv, 330; Underhill, *ibid.*, 1909, iv, 330.

agrees very well with the fact that in no other disease is there so great a diminution in the amount of chlorin as in croupous pneumonia, where exudation is very acute. The author has found a decrease of chlorids in the blood, which is in accordance with this view. A third assumption is that the chlorids are kept back as a sequence of the supposed retention of water in fever. Probably several of the above-mentioned factors act together in febrile disturbances to diminish the chlorids in the urine. In pneumonia the retention of chlorids in the exudate is probably the most important factor.

It is practically important, however, to remember that in febrile diseases any improvement in the condition will increase the amount of chlorids in the urine, and often before any improvement is indicated by the thermometer—*e. g.*, in pneumonia. Any great diminution in the amount of chlorids in non-febrile disorders always points to a serious condition. On the other hand, there are some very severe general conditions (the author has paid particular attention to this in circulatory disorders) in which no diminution of chlorids is observed.

A pronounced diminution or absence of chlorids in the urine in a febrile disorder will always suggest pneumonia, because, as has already been mentioned, the greatest degree of diminution is reached in this disease.

According to Emerson, the chlorin elimination may be used for the differential diagnosis between meningitis, when the chlorids are markedly decreased, and typhoid, when only a relatively small decrease takes place. Marked decreases have been observed by Emerson in pyemia, puerperal fever, cholera, and acute rheumatic arthritis. An increase was observed in cirrhosis of the liver. In nephritis, according to Achard and Löper, the excretion of chlorids is lower the more acute the condition. The excretion is the least disturbed in contracted kidney.

For practical purposes an approximate estimation of the chlorids, made as follows, will suffice: A specimen of urine in a test-tube is acidified with about 10 drops of pure nitric acid. Then a single drop of silver nitrate solution (1 : 10) is added. If the chlorids are normal, a solid ring, a ball, or one or more compact lumps of silver chlorid form and settle to the bottom; if diminished, only a more or less intense cloudiness arises. With a little practice the relative amount of chlorids may be judged by this simple test. Nitric acid is employed because it precipitates any protein present, which otherwise would be precipitated by the silver solution, and might thus lead to deception; and also because it prevents the precipitation of silver phosphate, which might be mistaken for the silver chlorid. If a large amount of protein appears after the addition of the nitric acid, it must first be removed by filtering or by letting it settle to the bottom before performing the chlorid test.

Volhard's procedure (titration with silver and ammonium sulphocyanate solution) is the most reliable method. It is described in connection with the Lütke-Martius method of estimating the hydrochloric acid of the gastric juice, and can also be employed for the urine. (See p. 455 et seq.) In employing this method it is best to use the urinary ash, since, if the silver solution is added to the urine, it precipitates not only the chlorids, but also the purin bodies, which would consequently give rise to a slight error.

uranium nitrate in the presence of potassium ferrocyanid, or the green color formed by tincture of cochineal with a surplus of uranium.

The following solutions are required:

1. A solution of uranium nitrate, which must be standardized with a solution of disodium phosphate of known strength. About 35 gm. of uranium nitrate are dissolved in a liter of water.

2. A solution of disodium phosphate, so prepared that 50 cc. shall contain 0.1 gm. P_2O_5 . This solution is prepared from the ordinary pure disodium phosphate; but since this salt contains a varying quantity of water, and consequently a varying amount of P_2O_5 , the solution must be standardized. This is done as follows: Twelve gm. of pure disodic phosphate are dissolved in a liter of water, and 40 cc. of the solution are titrated with $\frac{N}{10}$ hydrochloric or sulphuric acid, alizarin red being employed as an indicator. The end-reaction corresponds to the moment when all the disodium phosphate is transformed into the monosodium phosphate, and is indicated by the red solution turning yellow. If the solution is correct—i. e., if 50 cc. contain 0.1 P_2O_5 —the 40 cc. should require 11.25 cc. $\frac{N}{10}$ hydrochloric acid before the end-reaction occurs. As a rule, more is required, and the original solution must consequently be diluted. For example, if 13 cc. $\frac{N}{10}$ hydrochloric acid are required, and x represents the amount of fluid to which the 40 cc. must be diluted, we have the proportion:

$$40 : 11.25 = x : \frac{13}{11.25}$$

$$\text{and } x = \frac{40 \times 13}{11.25}$$

The sodium phosphate solution must then be so diluted that every 40 cc. is brought up to the volume x . If the solution contains too little phosphate, it must be concentrated by evaporation according to a corresponding proportion.

3. Acetic acid sodium acetate solution: One hundred gm. of sodium acetate are dissolved in 800 gm. of water, 100 cc. of a 30 per cent. acetic acid solution are added, and the mixture is diluted to 1 liter.

4. Potassium ferrocyanid solution: 10 : 100 water or tincture of cochineal. The latter is prepared by dissolving 6 gm. of powdered good cochineal in a mixture of 300 cc. of distilled water and 200 cc. of alcohol. The mixture is kept at an ordinary temperature for several hours, during which time it is frequently shaken and is then filtered.

Preparation of the Uranium Nitrate Solution.—Fifty cc. of the prepared solution of sodium phosphate are placed in an Erlenmeyer flask, treated with 5 cc. of the acetic acid sodium acetate solution, and heated to the boiling-point. A solution of uranium nitrate (35 : 1000) is now added from a buret as long as there is a distinct precipitate formed. The solution should now be tested after the addition of every $\frac{1}{2}$ cc. by taking a drop of the fluid out of the flask by means of a glass rod, and mixing it upon a porcelain plate or on a special paper prepared for the purpose by Schleicher and Schüll, with a drop of a potassium ferrocyanid solution. The end-reaction is the appearance of a reddish-brown color. A simpler method of attaining the same end is to add several drops of the tincture of cochineal to the fluid in the flask, bring it to the boiling-point, and add the uranium nitrate solution until a permanent pale-green color is obtained after mixing and reheating. It is now known how much uranium nitrate solution is necessary for the precipitation of 50 cc. of the sodium phosphate solution, and the uranium solution is to be diluted so that exactly 20 cc. will precipitate 50 cc. of the sodium phosphate solution. The 20 cc. of uranium solution are then equivalent to 0.1 P_2O_5 , or 1 cc. is equivalent to 0.005 gm. P_2O_5 . This varies somewhat according to the amount of uranium solution which is used. For this reason the standardization is performed with phosphate solution which corresponds fairly closely to the phosphoric acid content of normal urine. Using 20 cc., the amount is, according to Emerson, 4.98 mg.; for 21 cc., 5 mg.; for 40 cc., 5.14 mg.

Estimation of the Total Phosphates in the Urine.—If proteins be present, they must be removed; sugar does not interfere with the reaction. We proceed with the urine exactly as we did in the preparation of the uranium nitrate solution—i. e., we titrate 50 cc. of the urine and 5 cc. of the acetic-acid sodium acetate solution at the boiling-point with the standardized uranium solution until the end-reaction is obtained with potassium ferrocyanid or cochineal. Every cubic centimeter of the uranium solution employed then corresponds to 0.005 P_2O_5 .

Separate Estimation of the Earthy Phosphaturia (see pp. 648 and 676), it is of interest of the earthy phosphates. The difference between the earthy phosphates then gives the alkaline phosphates we proceed as follows: 100 cc. of ammonia; the mixture is allowed to stand for two days, then filtered, and washed with ammonia water. The filtrate is then poured into a glass rod, and the precipitate is washed into a beaker. The precipitate is then dissolved by heat in as small a quantity of acetic acid as possible, and the mixture is titrated with the uranium solution to estimate the total phosphates.

QUANTITATIVE ESTIMATION OF SULPHURIC ACID COMBINED WITH ORGANIC SUBSTANCES

Although the total amount of sulphuric acid in urine is of little clinical importance,¹ the amount of the sulphuric acid united with organic substances—the so-called ethereal sulphates is of much greater importance.

We can estimate sulphuric acid proper in urine by titration, because in a urine which is entirely free from sulphates, barium solutions will precipitate sulphuric acid as barium sulphate; whereas in the presence of organic substances, the sulphuric acid will be freed from its combination with the inorganic sulphuric acid. By subtracting the amount of sulphuric acid proper from that of the total sulphuric acid, the amount of sulphuric acid combined with organic substances may be obtained.

A process giving an approximate idea of the amount of sulphuric acid combined with organic substances has been suggested by Emerson.

In a large test-tube holding 25 cc. of urine, add 1 volume of an acid barium chloride solution. The sulphates are precipitated as barium sulphate. If the precipitate is denser, the sulphates are in greater amount; if the precipitate is less dense, the sulphates are diminished. The precipitate occupies about half the test-tube. If the precipitate be filtered off, and the filtrate to the filtrate and the whole boiled, a residue will be left due to the ethereal sulphates.

FOLIN'S METHODS FOR TOTAL SULPHUR, ETHEREAL SULPHUR, AND NEUTRAL SULPHUR

Total Sulphur.—Place 25 cc. of the urine in a beaker, and add 3 gm. of sodium peroxide. Evaporate on a water-bath, and heat carefully over a flame until it smells of the flame and allow it to cool. Moisten the residue with 10 cc. of water, add 1 gm. of sodium peroxide to the residue, and fuse. The fusion must be done carefully at first as the melt has a tendency to boil. Allow the crucible to cool thoroughly, and add 100 cc. of water. Boil on the water-bath for some time, to dissolve the residue. Pour the crucible into a flask and dilute to 250 cc. Add 5 cc. of 10% hydrochloric acid, and boil for thirty minutes. The solution is then clear. To the clear solution add 5 cc. of dilute alcohol (1 to 10). The addition of a few drops of methyl-orange solution will give a pink color.

¹ The so-called total sulphuric acid of the urine is the sulphuric acid in the ordinary sense of the word, and of sulphuric acid combined with organic substances.

chloric acids are present in the solution. In their absence the solution will not be decolorized. If the boiling has been sufficiently prolonged, this will be the case. The solution is now filtered, allowed to cool, and to it are added, by means of a test-tube or a thistle-tube drawn out to a fine point, 10 cc. of 10 per cent. barium chlorid solution. The addition of the 10 cc. should occupy about three minutes. During this time the solution is not stirred. The beaker is allowed to stand for two days, and filtered off on a Gooch crucible, ignited, and weighed. If Gooch crucibles are not available, the precipitate may be filtered through a Schleicher and Schüll ashless filter-paper, washed with cold water, ignited, and weighed.

Total Sulphates.—Place 25 cc. of the urine in a 200 to 250 cc. flask, add 20 cc. of dilute hydrochloric acid (1 to 4), and boil the mixture gently for twenty to thirty minutes. The mouth of the flask should be covered with a watch-glass. Cool and dilute to 150 cc. with water. Add 10 cc. of a 5 per cent. solution of barium chlorid, as in the total sulphur estimation. Allow the mixture to stand for at least one hour, and filter through a Gooch filter. Ignite and weigh.

Inorganic Sulphates.—Place 50 cc. of urine and 100 cc. of water in a 200 cc. flask. Add 10 cc. of dilute hydrochloric acid (1 to 4), without boiling, add 10 cc. of 5 per cent. barium chlorid solution drop by drop, and proceed as in the determination of total sulphates.

Ethereal Sulphates.—The difference obtained between the results obtained for total sulphates and for inorganic sulphates gives the amount of ethereal sulphates present in the urine.

The normal daily excretion of total sulphates in the adult amounts to 1.5 to 3 gm. of SO_4 , and parallels the quantity of protein decomposed. The normal ratio of the daily amount of the total sulphates to the daily quantity of urea is about 1 : 5, while the ratio of the quantity of the ethereal sulphates to that of the remaining sulphates is about 1 : 10.

It is of some diagnostic interest that in many putrefactive processes phenol-like substances are formed in the urine, and at this time the ethereal sulphates are increased. Experiments which have been made to determine to what extent this may be used as an index of intestinal putrefaction have not been conclusive. Neither the relation of the ethereal sulphates to the total sulphates nor the absolute amount of the excretion give any decided information. The reason for this is that the ethereal sulphates are not altogether dependent on putrefactive processes, for other factors, such as the food and the breaking down of tissue, yield these substances in the urine. (See Jaffé, *Indicanurie*, Deutsche Klinik, 1907, vol. xi, p. 203.)

QUANTITATIVE ESTIMATION OF AMMONIA IN URINE

The normal amount of ammonia contained in adult urine, according to Neubauer, varies in twenty-four hours between 0.3 and 1.2 gm., and averages 0.7 gm. A meat diet, the ingestion of radishes, the breathing of air saturated with tobacco smoke, and the taking of ammonium salts and mineral acids as medicaments increase the daily amount of ammonia excreted.

The quantitative estimation of ammonia in the urine may be of clinical interest under certain circumstances. We know that the human organism, like that of carnivora in general, reacts to an increased ingestion of acid or increased acid formation by an increased production of ammonia, which serves the purpose of holding the otherwise injurious acids in combination. Consequently, the amount of ammonia salts contained in urine is an important indicator of acid metabolism.

The daily quantity of ammonia excreted is increased pathologically in diseases of the liver and in acute febrile diseases, such as pneumonia and typhoid fever. The increase is usually at the expense of the urea. In affections of the liver there is a specific impairment of its urea-forming function; in febrile diseases the increased quantity of ammonia is the effect of the increased formation of acids in consequence of the augmented decomposition of protein. The increase in the amount of excreted ammonia is most striking in diabetic acidosis.

This is of practical importance in diabetes mellitus. The increased elimination of ammonia led in this case to the discovery that certain diabetic urines con-

volume of standard sulphuric acid. The distilling flask is heated on the sulphuric acid. The distilling flask is heated on the water-bath at 60° C. At this temperature all the ammonia is distilled off and collected in the acid. The acid remaining unneutralized is determined with standard alkali. From this the amount of ammonia distilled off is calculated.

METHOD FOR AMMONIA ACCORDING TO FOLIN

Place 25 cc. of urine in an areometer cylinder about 30 to 40 cm. high. Add about 1 gm. of dry sodium carbonate and a little kerosene oil to prevent foaming. Insert into the neck of the cylinder a rubber stopper provided with two perforations, into each one of which passes a tube, one of which reaches below the surface of the liquid. The shorter tube (10 cm. in length) is connected with a calcium chlorid tube filled with cotton-wool, and this tube is connected with a gas washing-bottle containing 20 cc. of decinormal sulphuric acid and 100 cc. of distilled water. A few drops of an indicator, either alizarin red or carminic acid, are added. To complete the absorption of the ammonia the gas washing-bottle is provided with a special tube which insures better contact of the air which passes through it with the acid. The other tube of the gas washing-bottle is connected with a good filter-pump, and air drawn through the apparatus for an hour and a half. The number of cubic centimeters of acid neutralized by the ammonia may be determined by direct titration with decinormal sodium hydroxid. This is one of the most satisfactory methods for the determination of ammonia which has yet been devised. Several determinations may be made simultaneously by connecting the set of apparatus in tandem.

QUANTITATIVE ESTIMATION OF THE β -OXYBUTYRIC ACID IN THE URINE

The quantitative estimation of β -oxybutyric acid is of great interest in diabetic acidosis. Stäubli¹ has shown that in benign cases of acidosis, in spite of a high content of acetone and aceto-acetic acid, the amount of oxybutyric acid in the urine is small. If this be the case, the estimation of this acid in the urine is a matter of considerable prognostic importance. The estimation of the acid by means of the polariscope is a practical clinical method. β -oxybutyric acid is levogyrate, and has a specific rotating power of 24.1, or of 20.6°, according to different authorities. Fermented urine is freed from protein and decolorized with lead acetate and ammonia or mercuric nitrate, and its rotatory power is then determined (p. 624 et seq.). If the 100 mm. tube of the polaristobometer is used (p. 625), Minkowski states that a rotation of -1° will correspond to $\frac{100}{20.6}$ per cent. of β -oxybutyric acid (about 5 per cent.). In this estimation we must naturally assume that the urine does not contain any other non-fermentable substances which are levogyrate, such as the combined glycuronates, etc. A positive Trommer's test with the fermented urine would point to their presence. The normal constituents of the urine which turn the plane of polarized light to the left, such as uric acid and kreatinin, do not disturb the test, because the rotation caused by them is very slight, and, besides, there is only a very small percentage of them in diabetic polyuria.

Magnus-Levy² regards the quantities obtained by this method as inaccurate, and thinks they are too large, but is unable to give a satisfactory explanation of the marked levogyration found in these cases.

Bergell³ (see Stäubli⁴) estimates β -oxybutyric acid by making 200 cc. of the urine alkaline with sodium carbonate and evaporating to a syrup. The urine is then made acid with phosphoric acid, and mixed with kieselguhr until it forms a dry powder. This is then extracted with ether in a Soxhlet apparatus for thirty-six hours. The ether residue is diluted to 20 cc., decolorized with animal charcoal, or with lead carbonate and hydrogen sulphid, and the acid estimated polarimetrically.

For clinical purposes the quantitative estimation of the excretion of ammonia is the best indirect means for determining the amount of β -oxybutyric acid excreted.

Darmstädter's⁵ method for the direct estimation of the β -oxybutyric acid

¹ Korrespondenzbl. f. Schweiz. Aerzte, 1908, No. 5.

² Arch. f. exp. Path., vol. xlii, p. 167, et seq.

³ Zeit. f. physiol. Chemie, xxxiii, 310.

⁵ Zeit. f. physiol. Chemie, 1902-03, vol. xxxvii, p. 355.

depends upon the fact that β -oxybutyric acid is soluble in water by concentrated mineral acids. The method of urine are rendered alkaline with sodium carbonate; the residue is dissolved in 150 to 200 cc. of water; 300 to 350 cc. are now distilled from this mixture for half hours, the fluid removed being replaced by water or three times with ether, the ether evaporated in order to remove any volatile fatty acids which are then dissolved in 50 cc. of water, the solution filtered and the filtrate added to a 10% sodium hydroxide solution: 1 cc. $\frac{N}{10}$ sodium hydroxide solution is equivalent to 1.21 β -oxybutyric acid.

Magnus-Levy did not find that in this process the β -oxybutyric acid is completely converted into crotonic acid.

Magnus-Levy¹ extracts the urine directly. 30 to 40 gm. of ammonium sulphate are added, and the mixture is extracted with ether. For large amounts of urine the extraction with ether is used, which allows one to operate on 30 to 40 gm. of urine. For smaller amounts one of the ordinary liquid extractions can be given. No fixed time for extraction can be given. In the extraction must be controlled. According to Magnus-Levy, the process takes about twenty-four hours,² the ether is removed through a dry filter, and allowed to evaporate. It is better not to heat the residue on the water-bath, as it may contain crystals of hippuric acid. To the residue an oil falls to the bottom which later becomes solid. The oil is filtered through a small filter and made up to 10 to 20 cc. of water. The liquid is then polarized. If the liquid shows any residue, the extraction may be stopped. The etheral extraction are perfectly clear, and are so sized at once in a 20 cm. tube. As the rotatory power is small, small amounts of the acid with consideration, 0.6 gm. of the acid, and of the solution, 0.4 gm. in 10 cc. of water will give a rotatory power. Urines containing more of the acid one must use a larger amount of the acid. Magnus-Levy gives the specific rotation of the acid as $[\alpha]_D^{20} = +1.5$.

According to Magnus-Levy, 60 gm. of β -oxybutyric acid when diabetic coma is not present, while in coma have been observed. The percentage found rarely exceeded 0.5 to 1 per cent.

The best indirect method for the clinical purpose is the estimation of the acid. This, of course, merely gives an idea of the amount of the acid.

QUANTITATIVE ESTIMATION OF THE AMOUNT OF β -OXYBUTYRIC ACID IN URINE

By the Estimation of Iodoform.—As acetone is the main source of β -oxybutyric acid, the estimation of acetone and β -oxybutyric acid is the same.

*Acetone Estimation.*³ According to Hülger and Lieben, in weighing the iodoform produced in Lieben's reaction, the iodoform is distilled, using an efficient condenser until 90% is treated with a considerable excess of sodium (See p. 600, Lieben's Reaction.) The precipitate is allowed to stand for twenty-four hours and then is filtered through a filter of cold water and dried over sulphuric acid in a desiccator. A wool filter is to be recommended, for then the water adhering to the glass-wool is removed.

¹ *Ergeb. d. inn. med. Kinderheilk.*, 1908.

² If a brown residue remain in the flask, it is the residue of the acid that does not dissolve in the ether. As a residue may be included in the residue, it is dissolved in ether and reextracted.

³ Huppert, *Harnanalyse*, 1898.

completed over sulphuric acid. One gm. of iodoform corresponds to 0.147 gm. of acetone.

It is simpler to extract the iodoform with ether. In the vessel in which the reaction has taken place one pours 20 cc. of alcohol-free ether. The contents of the vessel are well shaken and 10 cc. pipetted off. This is allowed to evaporate in a weighed dish. The residue is dried over sulphuric acid and weighed.

Messinger and Huppert estimate the amount of iodoform produced volumetrically.

Twenty cc. (with urine poor in acetone, 100 cc.), and distilled with 2 cc. of acetic acid 50 per cent. The distillate is redistilled after the addition of 1 cc. of sulphuric acid (1:8). The distillate is treated with an excess of decinormal iodine solution¹ and sodium hydroxide in excess. After standing a little while the excess of iodine is estimated with decinormal sodium thiosulphate solution. The details of the methods are given in Neubauer and Vogel, *Harnanalyse*, 0898. Magnus-Levy points out (*Ergebnisse der inneren Medizin und Kinderheilkunde*) that both the decinormal iodine solution and the sodium thiosulphate solution are liable to change their strength, so that frequent controls of the strength of the solutions should be made.

Acetone and aceto-acetic acid usually occur together in the urine; hence the iodoform obtained includes not only that derived from the preformed acetone, but also that derived from the acetone formed from the diacetic acid by the distillation. Acetone and aceto-acetic acid are about equally valuable in diagnosis (see p. 598), so this is no particular disadvantage. Besides, as we have no exact method of determining the amount of aceto-acetic acid, the estimation of the acetone is the only way in which we can obtain an approximate idea of the amount of aceto-acetic acid.

If one wishes to estimate the preformed acetone, this may be done according to Embden² or to Folin³ by taking the acetone out of the solution containing it by means of a current of air. Magnus-Levy is not certain that in this method, for the performance of which Folin gives special directions, a certain amount of aceto-acetic acid is not converted into acetone.

ESTIMATION OF ACETONE ACCORDING TO ECKENSTEIN AND BLANKSMA

This method has been reported upon by S. Möller at P. Bergell's suggestion. It gives good results for clinical purposes.

Two hundred cc. of urine are distilled after adding 5 cc. of 33 per cent. sulphuric acid. The distillation takes about forty-five minutes. To the distillate, which will usually be about 100 to 120 cc., 0.5 to 1 gm. of paranitrophenylhydrazine, dissolved in 5 to 10 cc. of glacial acetic acid, are added. The mixture is diluted with 2 volumes of water. This amount is sufficient for all but exceptional cases of diabetes. It may be necessary to filter the solution of the hydrazone before it is added to the

¹ The requisite solutions are prepared in the following way: Decinormal iodine solution is obtained by dissolving 12.7 gm. of iodine and 20 gm. of potassium iodide in water and diluting to 1000 cc. The solution is so prepared that 10 cc. of the solution are decolorized by 10 cc. of decinormal sodium thiosulphate solution. Starch paste is used as an indicator. Decinormal sodium thiosulphate solution is prepared by dissolving 25 gm. of the crystalline salt (1000 cc. = $24.83 \text{ Na}_2\text{S}_2\text{O}_3 + 5\text{H}_2\text{O}$). The thiosulphate solution is titrated with decinormal potassium dichromate in the following way: A solution of 1 gm. of potassium iodide in 5 cc. of water and 2 cc. of 25 per cent. hydrochloric acid is treated with 10 cc. of decinormal potassium dichromate. The resulting mixture is diluted to 200 cc. with water, a little starch paste added, and titrated with the sodium thiosulphate solution. If the solution is exactly decinormal, 10 cc. of thiosulphate are necessary to discharge the blue color. If less be used, the thiosulphate solution must be diluted to the proper concentration or a factor used.

² *Verhandl. Cong. f. inn. Med.*, 1907. ³ *Jour. Biol. Chem.*, 1907, iii, p. 177.

urine. After some minutes, in the presence of ac formed. The precipitation is complete in half an l be avoided. The precipitate is filtered off on a ha stant weight at 80° C., and weighed. The amou plied by 0.3 gives the amount of acetone. Accor hydrazones remain in every 100 cc. of filtrate. As t a correction for this solubility must be made. M best for clinical purposes.

ESTIMATION OF ACETONE AND ACETO-ACETIC

[The same type of apparatus is used for Folin method for ammonia. (See p. 653.)

Into an areometer cylinder are introduce be examined, 10 gm. of sodium chlorid, 10 c phoric acid solution, and a little kerosene flask are introduced 150 cc. of water, 10 cc hydroxid solution, and a definite volume of The cylinder and the absorption flask are (the ammonia method, and a current of air d is removed from the urine saturated with current and is drawn into the alkaline iodin & into iodoform. The time taken by this oper To the mixture in the absorption flask are a hydrochloric acid, and the excess of iodin sodium thiosulphate and starch.

Aceto-acetic Acid.—The combined acetone be determined by the Huppert-Messinger found by Folin's method subtracted from gives the amount of acetone due to aceto-a

ESTIMATION OF β -OXYBUTYRIC ACID A

Introduce into a 500-cc. volumetric flask be examined. The amount of urine used w of β -oxybutyric acid which is contained in giving a strong ferric chlorid reaction, 25 to It is desirable to use such a volume of urin of acetone. To the urine is added an exce 10 cc. of ammonium hydroxid. It is necess of the lead salt has been added. The mixtu mark, shaken thoroughly and filtered throu of the filtrate are distilled after the addition and 15 cc. of concentrated sulphuric acid an bumping. About 200 to 250 cc. of dis distillate contains, in addition to acetone f and aceto-acetic acid, certain volatile acid alkaline, and a second distillation made, t the acetone from acetone and aceto-acetic t by the iodin method.

The residue from the urine containing all the β -oxybutyric acid, and must now be into acetone. The residue is diluted and 0.5 ate added. It is then distilled from a flas funnel, and water added gradually to mal tilled over. Instead of water, one may use

potassium dichromate. After about 500 cc. of distillate have been collected, the distillate is redistilled, after the addition of 20 cc. of 3 per cent. hydrogen dioxid and sufficient potassium hydroxid to make the solution alkaline. Collect 300 cc. of distillate and estimate the amount of acetone with iodine and thiosulphate; 1 mg. of acetone is equivalent to 1.794 mg. of β -oxybutyric acid.

The above methods for the determination of acetone, aceto-acetic acid, and β -oxybutyric acid are more accurate than any others that have hitherto been described, and should be used for the study of the clinical problem of acidosis.—C. G. L. W.]

ESTIMATION OF THE TOTAL DRIED RESIDUE OF URINE

Sometimes this is of clinical interest. The author has demonstrated that a watery diuresis—*i. e.*, diuresis produced by an increased consumption of water, more especially from a subcutaneous or intravenous infusion of salt solution—will increase the twenty-four-hour excretion of solids in the urine. The method of determination is very simple. Fifty cc. of urine are measured into a weighed dish and evaporated to a syrupy consistence over a water-bath at a very moderate temperature (not over 60° C.), after adding 2 or 3 drops of acetic acid, then dried further in a vacuum over sulphuric acid to a uniform weight. The urine must not be heated above 60° C., as otherwise ammonia will be given off from the urea. The addition of acetic acid is necessary to combine with any ammonia which may have been liberated in spite of the care taken when evaporating.

It is still safer to dry entirely in a vacuum without heating, but then a much smaller amount of urine (at most, 5 cc.) should be employed. A drop of acetic acid is added to the urine in a very shallow dish, along with a generous amount of sulphuric acid, and it is then allowed to dry in the vacuum to an absolute weight. If necessary, the sulphuric acid can be replenished and the vacuum restored by repeated exhaustion.

An approximate estimation of the total amount of solids in 1 liter of urine can be obtained from the specific gravity of the urine. (See p. 551.)

URINARY ACIDIMETRY AND ALKALIMETRY

(Determination of Acidity and Alkalinity. Estimation of the Acidic and Basic Points.)

The conditions which affect the reaction of the urine have already been discussed upon p. 556 et seq. The reaction of individual specimens of urine varies; hence the degree of acidity must be determined from a specimen of the mixed twenty-four-hour urine. The addition of a few drops of chloroform, or keeping the urine upon ice, will prevent any change in the reaction due to decomposition.

The quantitative estimation of the reaction by means of acidimetry or alkalimetry is accomplished by titration. Certain objections have been constantly raised in reference to the possibility of titrating the acidity of the urine, and these objections have also been fully considered in Nægeli's¹ experiments upon this subject, which were undertaken at the author's request. The author fully realizes the theoretic justification of all these objections, which arise from the fact that the end-reactions of the titration of the phosphoric acid are theoretically never distinct, and not always so even from a practical standpoint. The reasons for this fact have been clearly explained by T. Heffter.² So long as the chemist gives us nothing better, however, we are forced to use these methods in practice, even though they are not strictly accurate, and Nægeli has at least shown that it is possible to obtain approximate values for the acidity of the urine by means of titration.

In view of the undeniable difficulties of titrating the urine acidimetrically, the author thinks it is entirely beside the mark to attempt to replace the classic conception of acidity by an entirely different one—namely, the concentration of the hydrogen ions—instead of trying to improve the method of titration. The acidity is not due to the concentration of the hydrogen ions, but to the number

can be ascertained only to the neutral point, not to the basic point, whereas the total basicity may be determined, because the moment when free acid appears, following the addition of $\frac{N}{10}$ HCl (acid point), is indicated sharply by alizarin red.

Leaving out of consideration the urates and oxalates, the sum of the values, according to alizarin and phenolphthalein, corresponds, approximately to the contents of carbonic and phosphoric acid molecules in the urine. Finally, the two titrations give an insight as to the amount of the bases which are excreted combined with phosphoric acid. If the urates, oxalates, and carbonates are not considered, this amount is approximately obtained when the value of the phenolphthalein titration is added to double that of the alizarin titration. In the titration with phenolphthalein, as much alkali equivalent is added to complete the reaction as there is in the phosphates corresponding to the formula NaH_2PO_4 , and appearing in the reaction; while in the alizarin reaction one-half as much acid equivalent must be added in order to bring about the end-reaction. This calculation contains considerable errors only when there are present in the urine relatively large quantities of carbonates, oxalates, or urates, which may enter into the reaction. This is seldom the case, however.

Urine which reacted alkaline to phenolphthalein could be titrated by means of $\frac{N}{10}$ HCl with the indicator and the neutralization point accurately determined if the alkalinity were caused by fixed alkalis. This condition, however, has never been observed. In general, a urine which reacts alkaline to phenolphthalein contains ammonium carbonate, and in this case the addition of $\frac{N}{10}$ HCl causes the formation of acid ammonium carbonate, which immediately decomposes and liberates CO_2 and NH_3 . The indicator, being much more sensitive to CO_2 than to NH_3 , becomes decolorized (by the CO_2) long before the NH_3 in the urine is completely neutralized—i. e., before all the $(\text{NH}_4)_2\text{NCO}_3$ is transformed into $(\text{NH}_4)\text{HCO}_3$. The obtaining of an accurate end-reaction with phenolphthalein under these conditions is therefore impossible. Actually, however, this difficulty presents no serious disadvantage, because the ammoniacal character of urine, with the exception of the presence of ammonium carbamate as the result of calcium feeding, is caused exclusively by the bacterial decomposition of urine. In such cases quantitative determinations have no interest. On the other hand, it is to be emphasized that the determination of the acid point—i. e., the point at which all the NH_4Cl is transformed into HCl—presents no difficulties. Such determinations acquire, under certain conditions, clinical interest in the consideration of the degree of bacterial decomposition of freshly voided urine in cystitis.

On the other hand, it is conceivable that titration with HCl in the presence of alizarin does not lead to accurate results if the urine contains large amounts of ammonium salts, as is the case in diabetic acidosis. Nägeli found in the titration of ammonium salts of dibasic acids—e. g., ammonium oxalate with HCl—that the change of color of the alizarin into yellow does not take place at the moment of the appearance of free acid, but as soon as the acid salts are formed. The color-change is also too gradual to allow of sharp reading. Nevertheless, this disturbance of the reaction does not come into play in the case of a monobasic acid, such as β -oxybutyric. In the normal condition of the excreted ammonium salts, these hardly effect the determination of the acid point. In cases where the ammonium content of the urine is excessive, the determination of the acid point can be performed as follows: In a portion of the urine the ammonia is quantitatively determined according to the Schlösing method (p. 652), or that of Krüger and Reich or of Shaffer or Folin, and then to another portion is added the equivalent amount of NaOH, sufficient to set the NH_3 free. This ammonia can be driven off by heat, and the solution then titrated in the usual way.

In practice the titration is carried out in the following manner: To 2 portions of 10 cc. of the urine are added respectively phenolphthalein and alizarin. The first is titrated with $\frac{N}{10}$ NaOH to the appearance of a permanent red color. To the second, $\frac{N}{10}$ HCl is added until the red color has changed to yellow. The color of the urine itself does not interfere in the titration to any noticeable extent, especially if there is placed alongside of the beaker in which the titration is being performed a second, for control, with equal amounts of urine and indicator to which no acid or alkali is added. Both solutions should be diluted to an equal extent. Strongly colored urine can be diluted or be decolorized by animal charcoal which has been tested and found to be neutral. The charcoal should be repeatedly extracted with boiling water until the washings are neutral. Even then one is not certain in

the use of this reagent, for certain not sharp and the cause is to be as the latter may be estimated and re as before described. For the techn see pp. 453 and 456. follows: In an Erlenmeyer flask, holding 150 cc., are placed 10 cc. of the fluid to be examined, 4 cc. of seminormal sodium oxalate solution, and 15 cc. of concentrated sodium chlorid. After the addition of the oxalate, some time is allowed to elapse in order to complete the precipitation of the calcium oxalate. The sodium chlorid solution is then added. Two similar solutions are prepared, the one being used for a comparison. If this be done, the change in color, even in dark urines, is quite distinct. A special process is necessary for urines when a precipitate of phosphates takes place. The solution of the phosphates in standard hydrochloric acid can only be done when the urine contains no carbonates. If carbonates were present, the carbon dioxide would be evolved and the acidity would then appear too small.

If one has to do with carbonates in the urine, the precipitate must be collected on a filter, dissolved in a known volume of standard acid, using methyl-orange as an indicator, and after the addition of sodium oxalate and sodium chlorid, retitrated with standard alkali. The alkali equivalent of the precipitate must be added to that obtained with the filtered urine.

THE ESTIMATION OF ACIDITY OF THE URINE BY TITRATION

O. Folin has informed me that he had published a method of estimating the acidity in the urine by titration quite similar to that of Moritz one year before the latter's publication (*American Journal of Physiology*, July 1, 1903, No. 5). This author too makes use of an oxalate, namely, oxalate of potassium, in order to prevent the formation of basic calcium phosphate during the titration, the principle of this method having been mentioned by Liebig and used since by Jäger.¹

He makes use of the same salt to avoid the difficulties arising from the presence of ammonia salts in the urine. Moritz employed for this purpose concentrated solutions of sodium chlorid. Folin, on the other hand, simply adds an excess of potassium oxalate, which, of course, exerts an action similar to that of the sodium chlorid. Folin has found that after the addition of an excess of potassium oxalate during the titration of acid fluids, almost the same quantities of alkali are necessary to produce a change of color in phenolphthalein as has been theoretically worked out, even though the fluids in question contain large amounts of ammonia salts; if the potassium oxalate is not added, on the other hand, the presence of ammonia salts leads to a marked difference in the amount of alkali necessary to produce the change in the color of the indicator.

Folin's method of estimating the total acidity of human urine is as follows: 25 cc. of urine are measured out with a pipet into an Erlenmeyer flask of 200-cc. capacity. To this are added 2 or 3 drops of 1 to 2 per cent. solution of phenolphthalein and 15 to 20 gm. of powdered neutral potassium oxalate. The mixture is shaken for about one minute and then immediately titrated with a decinormal solution of sodium hydroxid until the appearance of a weak but distinct rosy tint. The flasks ought to be shaken during the titration in order to keep the fluid as perfectly saturated with the oxalate as possible.

FOLIN'S METHOD OF ESTIMATING THE ACIDITY OF THE URINE DUE TO ORGANIC ACIDS. (*The Content of Urine in Organic Acids.*)

In a second noteworthy paper published in the *American Journal of Physiology*, 1905, No. 1, p. 102, Folin brings forth a great deal of evidence showing that in spite of traditionally accepted assumption phosphoric acid does not exist in the urine in the form of a mixture of dibasic and monobasic phosphates, but only as a monobasic phosphate. Moreover, the total acidity of the urine is greater than that

¹ *Centralbl. f. d. med. Wissen.*, 1902, p. 641.

caused by the presence of the acid phosphates is due to the presence of organic acids. and in my opinion Folin's evidence is of the acidity caused by the organic acids. mineral acids is of great clinical importance. mentioned above, he described a somewhat of estimating the acidity of the urine due to the values obtained by this method, which in this place, from the figures giving the acidity is enabled to find the acidity due to the

CRYOSCOPY OF THE URINE; OSMOTIC PRESSURE AND ULAR CONCENTRATION

PREFATORY

According to van t'Hoff, substances in solution behave exactly like the molecules of a gas, of the containing vessel by their endeavor to fill the possible space. This pressure of dissolved substance, according to van t'Hoff, corresponds to the pressure which a gas or vapor would exert in the same space. From this it follows that the dependence upon the temperature is the same as in the law of Gay-Lussac, and also that solutions which contain the same number of molecules in the same space, according to Avogadro's law, exert the same pressure. If it will also be found that just as every gram of a substance which weighs as many grams as the quantity which weighs as many grams as —in a space equivalent to 22.4 liters at 0° C. —so also that solutions which contain 1 gram of a substance in 22.4 liters of fluid possess an osmotic pressure of 1 atmosphere. If 1 molecule be dissolved in a liter of water, the osmotic pressure, according to Mariotte's law, will be 22.4 atmospheres. From this it follows that osmotic pressure is directly proportional to the concentration of the solution, for example, possesses double the osmotic pressure of a solution. These laws, however, apply only to electrolytic substances, such as acids, bases, and salts which dissociate into ions, and a comparison of the osmotic pressure of the ions shows that in such solutions the osmotic pressure is due as it is by the molecules (Arrhenius, van t'Hoff). In a dissociated solution is consequently proportional to the number of molecules and of the ions. The osmotic pressure of sodium chlorid, unlike that of a sugar solution, is less than half of the osmotic pressure of a 1 per cent solution, as they are more strongly dissociated and contain more ions than concentrated solutions.

Under ordinary conditions, osmotic pressure is the pressure of a gas confined within a vessel. The effect of osmotic pressure by carrying out the experiment is if we place a watery solution of a substance in a vessel with walls which will allow the passage to water. In other words, a "semipermeable" membrane. The dissolved molecules will become separated from the water which penetrates the membrane from without. The effect becomes manifest, and there is a distention of the vessel in the ordinary sense of the word. The latter is due as a result of the "attraction of the solution" but it does not indicate the theoretic point in the experiment. The "attraction of the solution" is equal to the osmotic pressure, since

experiment until the hydraulic pressure has become equal to the osmotic pressure. The osmotic pressure of a watery solution may consequently be measured hydraulically by placing the particular solution in a tube, the lower end of which is closed by a membrane that allows the water, but not the dissolved substance, to pass through it, and then placing the lower portion of this tube in a vessel of distilled water. The water passes into the tube through the pores of the membrane, and the solution continues to be diluted until the hydrostatic pressure in the tube becomes equal to the osmotic pressure of the original solution. In this experiment the final height of the column of fluid is consequently the measure of the osmotic pressure, and the latter may be correspondingly expressed in atmospheres. This method, however, in actual practice is not easy, and the osmotic pressure of solutions is usually determined in another manner, as will presently be shown.

METHOD OF DETERMINING THE FREEZING-POINT

In medicine we are chiefly concerned with the determination of the osmotic pressure of the blood and of the urine, more rarely with that of other fluids of the body. The best method for this purpose, and the one which is almost exclusively employed, is the method of determining the freezing-point, or cryoscopy. The method depends upon the fact, discovered by Raoult, that the lowering of the freezing-point of a watery solution, as compared with the freezing-point of distilled water, is proportional to the molecular concentration of the solution—i. e., to the number of molecules contained in a unit of volume, and consequently (see above) to the osmotic pressure. We must, nevertheless, remember the fact, pointed out by Arrhenius and van t'Hoff, that in partly dissociated solutions the ions have the same values as the undivided molecules in determining osmotic pressure, and consequently in the lowering of the freezing-point. It will be seen from what has been said that if one watery solution has a freezing-point of -1°C. , and another has one of -0.5°C. , then the first solution possesses double the osmotic pressure of the second. The lowering of the freezing-point is usually designated by Δ , and the minus sign is omitted. A solution which freezes at -1°C. consequently has a lowering of the freezing-point, $\Delta = 1$. From the previously stated fact, that a gram-molecule dissolved in a liter of water has an osmotic pressure of 22.4 atmospheres, it is easy to estimate the osmotic pressure in atmospheres from the lowering of the freezing-point. Since a gram-molecule dissolved in a liter of water produces a lowering of the freezing-point indicated by $\Delta = 1.85$, it follows that a lowering of the freezing-point of 1.85 corresponds to an osmotic pressure of 22.4 atmospheres. Moreover, since the lowering of the freezing-point and the osmotic pressure vary proportionately, the correct osmotic pressure of any solution may be estimated in atmospheres from the freezing-point of the solution. The blood, for example, has an osmotic pressure of about 7 atmospheres. From a medical standpoint, however, we are more interested in the deviation of the fluid examined from the normal—i. e., in a relative value—and consequently the freezing-point is not usually calculated in pressure values, but the osmotic pressure is simply indicated by the lowering of the freezing-point.

Fig. 252.—Beckmann-Heidenhain's apparatus for determining the freezing-point of a solution

The freezing-point is usually determined by means of Beckmann's apparatus, Heidenhain's modification of which is shown in Fig. 252.¹ The instrument is

¹ Recently it has been suggested to use the cold produced by the evaporation of a volatile liquid, such as ether. The evaporation is hastened by means of a foot-bellows. The apparatus constructed by Röthlisberger, in Baden, seems to be more convenient. In this apparatus the air-current is produced by means of a water suction-pump. The current may be so regulated that practically a constant temperature is produced. (See Röthlisberger, Münch. med. Woch., 1905, No. 22.) The apparatus may be obtained from M. Schärer, A. G., Bern. It costs 65 francs.

composed of the following parts: *a* is a jar perforated in the middle. This jar holds by the strong wire loop (*c*). The opening agent glass (*d*), in which the actual freezing-cork. This freezing-vessel has a lateral pipe for the "inoculation of the fluid" will suit vessels *d* and *e* there is an inclosed layer of the cold to act gradually upon the fluid divided into hundredths of a degree, is a perforated cork, which also gives passage to a thermometer of the original apparatus. In physical experiments it must be used not having an entirely different freezing-point of which may be omitted, the amount of mercury or diminished from a specially constructed so that the freezing-point of the particular solution. The freezing-point of the pure solvent solution. The difference obtained is the difference of a degree.

This procedure with the original instrument for clinical purposes, and, as we have to usually employ a thermometer with a fixed point at the upper end of the scale, and corresponding water (see figure). Below this point the scale is fixed. The upper end of the capillary thermometer instrument is exposed to higher external pressure late in this expansion and not break the excellent quality and adapted for clinical use. The instrument factory of Götze, Hertelstraße 10, this firm has supplied an instrument with a fixed point in order to determine the freezing-point since we frequently have to do with a fixed point in the examination of the blood.

Since, in time, all thermometers vary the zero mark occasionally, even though correct. This is done by determining the freezing-point of the instrument, and, when it does not agree with the correction to all subsequent readings. In any distilled water at random. After a certain amount of alkali also takes up a certain amount of alkali to cause a distinct lowering of the freezing-point of the water employed must, at least, be fresh. In this distillation the receiver should be one which has been freed from soluble salts. It is desired to verify not only the zero mark of the maker of the instrument, but also done by also determining the freezing-point of the solution. According to Hamburger, the freezing-point of the instrument be correct, this is the necessary correction for the zero mark.

In the determination of every freezing-point that small particles of mercury are not at the bottom of the thermometer, since, if this is the exclusion of this part of the mercury be examined with a lens before every determination of mercury are found, they must be united with the mercury or by warming the instrument.

In determining a freezing-point the thermometer must be correctly prepared. It should not be to Hamburger,² is one of 3 parts of finely ground calcium chlorid; this is placed in the jar, and sufficient to bring about -3°C . If the temperature rises

¹ See Cohen, Vorträge über physikalische

² Osmotischer Druck und Ionenlehre

amount of ice and sodium chlorid in the given proportion should be added. If R  thlisberger's apparatus is used, where cold is produced by the evaporation of ether or carbon disulphid, the current of air is so regulated as to produce the required temperature. The fluid to be examined is now placed in the freezing-tube, and the thermometer and the platinum stirrer subsequently introduced. Care must be taken that the mercury reservoir of the thermometer is completely surrounded by the fluid, so that it is entirely submerged, and does not come in contact with any portion of the freezing-tube. The freezing-tube is then inserted into the reagent glass in the cover of the battery jar, so that it is surrounded by a uniform layer of air. The fluid in the freezing-tube must be kept in constant motion by gentle, but interrupted, movements of the platinum stirrer (*h*). The fluid must not splash. The mercury soon commences to sink in the thermometer, leaves the upper expanded portion, enters the capillary tube, and quickly falls to a point more or less below the freezing-point (excessive cooling), and then suddenly rises to a definite point, at which it remains stationary for some time. This point is the freezing-point of the fluid examined, and is read off. At this time needles of ice commence to form in the fluid, and it gradually becomes solidly frozen. When this has happened, the mercury commences to descend again. This complete freezing should not be waited for, however, but the determination should be repeated immediately after the mercury has ceased to ascend, by taking out the freezing-vessel, holding it in the hand, and stirring the fluid constantly until the mercury commences to ascend, when the freezing-vessel is again introduced into the reagent glass (*d*), and the freezing-point again determined as before. In warming the freezing-vessel for the purpose of repeating the determination all the crystals should not be melted—i. e., the temperature must not reach 0° (since the crystals consist of pure water)—because errors would arise if the fluid were subsequently "inoculated" with small pieces of ice (see below). When three determinations have been made, one immediately after the other, the average of the three is taken as the final result.

In order to determine correctly the freezing-point it is important to avoid excessive cooling (see above), since large masses of ice will form, and as these consist of pure water, a more concentrated solution remains, which gives a lower freezing-point corresponding to its higher osmotic pressure. The error of excessive cooling is avoided, first of all, by compounding the freezing-mixture so that its temperature is not too low. The safest way would be to compound it so that its temperature would be but a few tenths of a degree below the expected freezing-point, which could be approximately determined in a preliminary experiment. This takes up too much time, however, since the cooling would proceed so slowly, and in addition it makes the necessary recognition of the descent and ascent of the mercury much more difficult. If the temperature of the freezing mixture be -3°C. instead of the very low temperatures so commonly employed previously, the chances of excessive cooling are considerably reduced. An additional means of avoiding excessive cooling consists of the introduction of a minute piece of ice into the fluid through the lateral prolongation at the moment when the mercury falls below the zero-point. In physical chemistry this is referred to as "inoculation" of the fluid with a piece of ice. This accelerates the formation of ice, and consequently diminishes the danger of excessive cooling. This would seem to dilute the solution, and consequently lead to false results; but this is not the case when the manipulation is correctly performed, because the piece of ice cannot melt if the temperature be below zero. This would be possible, however, if the fluid were warmed in the hand to the zero point in making the second and third determinations. This must be avoided, as has been previously pointed out, and no error will then result if the fluid be repeatedly "inoculated." It will readily be understood that the fluid is useless for subsequent determinations after it has become thoroughly melted. In the author's experience he has found that "inoculation" is necessary if the temperature of the freezing-mixture be not more than 3°C. below the expected freezing-point, since in this manner the excessive cooling is avoided.

EMPLOYMENT OF CRYOSCOPY FOR THE STUDY OF THE RENAL FUNCTIONS

Since the determination of the freezing-point furnishes us with a simple and clinically applicable method of estimating the osmotic pressure, and consequently the molecular concentration of a fluid, this method of examination has been applied to the urine and to the study of the functions of the kidney. By this method it has been attempted to determine not only the total amount of work done by both kidneys, but also, by the practice of ureteral catheterization or by Luys' method of separation of the urines (see p. 558 et seq.), to compare the functions of the two

kidneys. Disregarding the excretion of water and not to be regarded simply as a filtration. The work of the kidney consists of excreting the waste from the blood, which has a much lower molecular weight than the blood. It is necessary for this purpose, and the pressure in the blood is consequently to be regarded as an osmotic pressure. We assume, as is frequently done, that the pressure from the blood represents the work done by both kidneys would be the daily excretion of urine, Δ the osmotic pressure of the blood. The result may be designated as the work of the kidneys. It should be remembered, however, that this is not complete nor exact. It is not complete because the kidneys excrete water, and also because the urine is diluted, which has a lower osmotic pressure than the blood. The work which the kidneys create no osmotic pressure, but the work that is not apparent as osmotic pressure. We know that different molecules require the same amount of energy. Although the difference in the molecular weight of the molecules, the potential energy stored up in the urine is the same. That the excretion of a molecule of sodium chloride requires more energy than is necessary for the excretion of a molecule of water. Probably exists in variations in the amount of energy required in the osmotic pressure of the urine. The work of the kidneys do not regard this point as a conclusion from the determination of the work of the kidneys by no means justified.

The utilization of the results of cryoscopic measurements of the activity of the kidneys is also complicated by the fact that in the study both of the mixed twenty-four-hour urine and of the mixed twenty-four-hour urine, there are large variations under normal conditions. It is difficult to find the point of the twenty-four-hour urine to be compared with the point of 2.7° C., and still greater variations in the conditions, dependent upon the ingestion of food.

¹ Should we assume that the production of the work of the kidneys exceeding that of the blood is the only work done by the kidneys, we should arrive at the paradoxical conclusion that the kidneys furnish a diluted urine perform no work (the latter if $\Delta - \delta$ is negative), while on the other hand, if the work of water in the urine in these cases, as is represented.

The author's opinion, that the excretion of water is the function of this organ, will possibly be accounted for by assuming that the kidney is extremely permeable to water, and that the work of the kidney is to supply energy for a simple filtration. It is not something quite specific, since a similar function is found in the body. We also have reason to believe that the function of the kidney is to supply energy for a simple filtration, since under physiologic conditions the kidney needs of the organism. A further proof of this is that water is furnished by the hypertrophic kidney, and the differences from the kidneys of wine-drinking animals is due to the effect of water and not to the effect of alcohol, as strikingly shown by the renal hypertrophy of the kidneys were not increased by the ingestion of alcohol become hypertrophic.

Another reason for the author's opinion that the work of the kidneys is no accurate measure for the work of the kidney is the ionization of the urinary constituents. Since part of this ionization occurs after the excretion of the case a concentrated urine become more dependent upon ions, or at least some of the work of the kidney.

large quantities of water, the difference between the freezing-point of the urine and that of distilled water may amount only to 0.11°C . (Köppe). In nursing infants the osmotic pressure of the urine is always less than that of the blood, and the lowering of the freezing-point may vary between 0.087° and 0.455° (Köppe). In any individual case the freezing-point may vary from day to day. Since there is no normal freezing-point for normal urine, we can draw conclusions in reference to the renal function in pathologic cases only when repeated examinations have shown the freezing-point to be constantly too high or too low, and when this extreme variation cannot be accounted for by anomalies in the ingestion of food or water. These difficulties are by no means overcome by basing the calculation upon the daily osmotic energy of the kidneys determined by $W = Q(\Delta - \delta)$ instead of upon the lowering of the freezing-point (Δ) or by employing the product of the daily excretion and the freezing-point of the urine ($Q - \Delta$). The formula $W = Q(\Delta - \delta)$ is more exact than the freezing-point alone, since it not only indicates the molecular concentration, but also measures the osmotic energy expended by the kidneys within twenty-four hours, while the product $Q\delta$ is a measure for the number of molecules excreted in a similar period of time. The previously emphasized objections to utilizing the freezing-point also exist here, since under normal conditions the number of excreted molecules and the product $Q\delta$ vary just as much as does the molecular concentration or the freezing-point. These results may consequently be employed for diagnostic purposes only when they are extreme, when they extend over long periods of time, and when they cannot be explained by an abnormal diet.

The most pronounced pathologic changes in the molecular concentration of the urine, in the daily osmotic energy of the kidneys, and in the product $Q\delta$ are encountered in nephritis, and particularly in the uremia which frequently results. In these cases the retention of urinary solids is very frequently manifested by an abnormally low molecular concentration and a consequent abnormally low daily excretion of molecules. Every improvement of the condition is indicated by an increase of both. According to Strauss, the chronic parenchymatous nephritis cases produce a more marked diminution of the daily excretion of molecules than do the interstitial, since in the latter cases the marked lowering of the freezing-point is more than compensated for by the increased quantity of urine excreted. In diabetes mellitus the osmotic pressure of the urine and the daily excretion of molecules are, of course, greatly increased by the amount of sugar in the urine.

The utilization of cryoscopy in determining the functional activity of a single kidney, the urine from which is obtained either by ureteral catheterization or by Luys' urinary separator, is accompanied by difficulties equally as great as those encountered in studying the mixed twenty-four-hour urine. The object of such examinations is to determine whether one kidney is functioning normally, and whether it will be able to do all the work after the removal of the diseased kidney. The conclusions drawn from the separate cryoscopic examinations of the urines of both kidneys in such cases, which have given rise to a large amount of literature, contain a great many sources of error, only the most important of which will be given. First of all, it by no means follows that the kidney remaining after the extirpation will do the same amount of work as before. Rather, if the diseased kidney still functionated to a certain extent, it is quite possible that the remaining kidney will respond to the increased excretory stimulus and compensate for the defect, even if it apparently did too little work before the extirpation. Upon the other hand, if the function of the healthier kidney be impaired, and yet sufficient to meet the needs of the organism when aided by the diseased kidney, it is possible that it may be insufficient when called upon to do the entire amount of work. These possibilities are not even mentioned in many of the publications upon the subject. Another frequent error is the false supposition that the freezing-point of the urine is the only measure of the functional activity of the kidney. As we have already seen, this is not the case, and the supposition of Kümmel, that a freezing-point of the urine below -1°C . indicates insufficiency of the viscus, is purely arbitrary.¹ Again, in order to reach more accurate conclusions, the quantity of urine excreted must also be considered. This cannot be correctly done, however, since it is not possible to collect the twenty-four-hours' urine from a single kidney. Great caution is also necessary when the results of the cryoscopic examination of the separate urines are employed for the purpose of comparing the functions of the two kidneys.

¹ Such conclusions would be more justifiable if all fluids were interdicted before the examination of the patient, in which case the approximately healthy kidney would always excrete a concentrated urine with a marked lowering of its freezing-point.

number of excreted molecules. In an entirely analogous manner the specific gravity of the urines (after the removal of protein, if present) obtained by ureteral catheterization or Luys' separator (see p. 558 et seq.) may be utilized in place of the osmotic pressure for the critical study of the urine of each kidney; but, owing to the impossibility of obtaining the total twenty-four-hours' urine, this procedure is open to the same objection previously mentioned in our consideration of osmotic pressure. The author must also take this occasion to claim that cryoscopy has not materially aided our diagnostic ability in reference to the critical study of renal activity, since all the facts learned by ureteral catheterization could also have been discovered by means of the specific gravity. Cryoscopy accidentally became popular and was given preference over the older method from an exaggerated idea of its value, just as all new methods are usually supposed to be an advance over those formerly employed. In addition to the fact that it is not necessary to remove protein, it must nevertheless be admitted that cryoscopy possesses one distinct advantage, particularly in the study of the separate urines, in that it requires a smaller amount of urine than is necessary for the determination of the specific gravity. Nevertheless, the chief advantage of the introduction of the new method has been that it has caused us to study these questions more carefully than was done by means of the specific gravity, since the latter method had not the charm of novelty. We shall subsequently learn that the case is quite different with reference to the cryoscopy of the blood, which is of special significance for general pathology and diagnosis.

How closely the conclusions obtained by means of the determination of the freezing-point of the urine correspond to those which the practical physician may deduce much more readily from the specific gravity is best shown by the statement of G. Fuchs,¹ that in a urine free from protein and sugar the lowering of the freezing-point may be empirically calculated by multiplying the last two figures of the specific gravity, carried to the third decimal place, by 0.075°C .

The far-reaching calculations and conclusions (based upon the freezing-point of the urine) which Koranyi² and others have formulated in regard to the freezing-point of the blood, as well as to the amount of sodium chlorid contained in both fluids, will not be discussed, since the author regards their fundamental principles as hypohetic, and in many respects erroneous.

SEDIMENTS AND TURBIDITY OF THE URINE

EXAMINATION OF URINARY SEDIMENTS; SEDIMENTATION; FILTRATION; CENTRIFUGATION; MICROCHEMICAL REACTIONS

Both urinary sediments and turbidity may be frequently enough recognized and characterized, without any microscopic examination, by their physical and chemical behavior. But a microscopic examination is necessary in most cases, especially for the differentiation of organized sediment. If the sediment be very abundant, a drop of the cloudy urine under the microscope will be sufficient; but generally the sediment is so scant that it is advisable to isolate and collect it by sedimentation, filtration, or centrifugation.

In concentrated urines with uratic sediments the microscopic examination of other constituents, and particularly of the organized elements, is frequently rendered very difficult by the presence of urates. In such cases the urates should be dissolved by heating the urine slightly and adding enough water to hold the urates in solution upon cooling. If this cannot be accomplished, which may be the case if uric acid has also been thrown down, both substances may be brought into solution by rendering the urine alkaline by the addition of a solution of soda. A borax solution may also be employed for the same purpose (see below). Such a solution of the precipitated urates and uric acid may be necessary not only for the direct microscopic inspection of the remaining

¹ Zeit. f. angewandte Chemie, 1902, p. 1072.

² Zeit. f. klin. Med., 1897.

deposits, but also as a preliminary centrifugation. In certain cases carbonates may similarly interfere with these sediments may be readily dissolved by hydrochloric acid.

For Sedimentation.—A tall, point the sediment is examined under the microscope settled to be plainly visible at the surface requires a few hours. The sediment at the upper end is closed with the finger. A portion of the finger a certain amount of sediment is removed. It is then closed again, removed, and the pressure is kept constant. A drop of sediment is placed upon a glass slide by slightly releasing the finger.

Strassburger has recently recommended alcohol, in order to hasten sedimentation of the fluid. But alcohol will precipitate many of the constituents recommended only where the amount of sediment is small. The presence of an amorphous precipitate will interfere with the microscopic demonstration of tubercle bacilli.

The urinary sediment changes rapidly. It should be examined as soon after settling as possible.

The various constituents of a sediment are distributed at different depths; hence, in many cases it is advisable to examine at varying depths of a sediment. A selection can be made while picking up the sediment.

To prevent bacterial decomposition, especially in the summer months, it is a good plan to add a small volume of chloroform to the water (1 : 200). To select a cool place for the sedimentation. Examination of organized sediments. Sediments in very concentrated or very dilute urine one-fifth to one-third its volume. This solution will not coagulate. It will act antiseptically. If bacteria are present, the addition of alcohol mentioned above is to be avoided. If the sediment is very scanty, the filtration method is better. Amount of the urine as possible is filtered. The sediment on the filter is picked up with the ordinary method. Urine remains.

The centrifuge¹ is now employed for obtaining the sediment. With it the sediment can be examined within a few minutes. Urine is perfectly fresh.

Many chemical reactions which require heat can be performed macroscopically with the aid of a microscope. In the latter case, e. g., to examine crystals, a drop or two of the agent is placed on the cover-glass, or perhaps sucked up with filter-paper at the other edge.

¹ Stenbeck, Zeit. f. klin. Med., 1892, 1891, p. 23.

The amount of the sediment is best estimated by von Posner's method of estimating the amount of pus present (p. 686). (See p. 681 et seq. in regard to the preservation of organized sediment.)

INORGANIC CRYSTALLINE AND AMORPHOUS SEDIMENTS AND MIXTURES

THE URATES

When the urine cools, urates may settle to the bottom, especially if the sample be concentrated, scanty, or strongly acid, *e. g.*, the urine of congestion and of fever, less often the urine of nephritis. The sediment will then present a fairly characteristic appearance, clay-colored, reddish yellow, brick red, or rose red (*sedimentum lateritium*). Sometimes it adheres to the wall of the urine glass as a thin coating. Unlike all other sediments, it dissolves extremely readily even with very gentle heating, and so can be accurately recognized. The addition of acid will also dissolve urate sediments with a gradual separation of uric-acid crystals. The addition of alkalis also dissolves the precipitate particularly easily, and often with the separation of phosphates. The ordinary urate sediments consist of a mixture of sodium, potassium, calcium, magnesium, and ammonium urates. Sodium urate predominates. With the exception of ammonium urates, the urates appear only in acid urine. They are formed by a double rearrangement between acid sodium phosphate and the neutral urates held in solution, from which acid urates are formed, which are not very soluble and become precipitated. Aside from these chemical processes, the cooling of the urine favors the separation of urates. That the mere cooling of the urine alone will not, however, produce the separation is shown by the fact that the sediment forms sometimes only a considerable time after the cooling, and also by the fact that a urate sediment usually does not entirely dissolve until the urine is heated to a temperature above that of the body.

Urate sediments often contain crystals of pure uric acid, which also arise from the double rearrangement mentioned above.

The peculiar pronounced brick- or rose-red color of some urate sediments arise from uroerythrin, a pigment as yet little understood. (Compare p. 582.) It seems to be formed to excess in certain febrile affections (acute rheumatism, pneumonia).

If a urine with a urate sediment is decomposed by ammoniacal fermentation, the sediment will be partly changed to acid ammonium urate. The latter is the only urate sediment which occurs in alkaline urine. (Compare p. 675.)

Under the microscope urate sediment appears as fine amorphous granules. If acetic acid be added, characteristic crystals of uric acid may be seen to shoot out from these granules (Fig. 253). Ammonium urate presents characteristically shaped crystals (Fig. 256, *b*). It occupies an exceptional position in occurring in alkaline urines together with phosphates and carbonates, and not as do ordinary urates. If a urine containing ordinary urates has been rendered alkaline by fermentation, one may find a mixture of alkaline and ammonium urates before the urine has actually become alkaline. Uratic sediments respond to the murexid test. (See p. 672, under Uric Acid.)

As already mentioned, the concentration of the urine and its acidity are particularly important in the formation of urate sediments. Urates

which uric acid crystallizes is almost without number. Hence, a brown-colored crystal always suggests uric acid. Uric acid may also be precipitated as colorless crystals. Both uric acid and urates reduce alkaline solutions of copper (Trommer's test). In case of doubt the *murexid* test may be performed with a few small crystals. The latter are heated with dilute nitric acid upon a porcelain plate or dish. Solution takes place with effervescence. After evaporation there remains a reddish residue, which turns a beautiful purple red upon the addition of a little diluted ammonia, due to the formation of ammonium purpurate (murexid). The addition of potassium hydroxid will change the color to violet. The urates also react to the murexid test.

Guanin, xanthin, and epixanthin, which give somewhat similar reactions to uric acid (see Xanthin, p. 678), do not occur as sediments in the urine, and are differentiated by their solubility in hydrochloric acid.

The most frequent shapes which the uric-acid crystals present under the microscope are depicted in Fig. 253.

If uric-acid crystals are observed in the sediment at the same time as amorphous urates, they have the same significance as the latter. They may be found in any concentrated urine. Rapid precipitation of purely crystalline uric acid without any amorphous urate in a comparatively abundant urine shows that it is strongly acid. Such a condition has nothing to do with the so-called uric-acid diathesis (gout and uric-acid calculus). Moritz has demonstrated that every individual crystal of uric acid has an albuminous ground-substance.

CALCIUM OXALATE IN THE SEDIMENT

These crystals occur both in pathologic and in normal urine. The sediment is usually scant, and recognized only when examined microscopically. An abundant oxalate sediment is often noticed after the ingestion of food-stuffs rich in oxalic acid (fruit, especially tomatoes, etc.). The appearance of oxalate crystals in the urine independent of a diet containing the salt of the acid has been termed oxaluria, and writers have indicated it as a special metabolic anomaly of the same general type as diabetes mellitus and gout. It must be pointed out that the condition is not always one of increased oxalate excretion, but may be that of a condition favorable to the precipitation of the crystal. Cases have, however, been examined where the analysis showed an increased excretion of oxalic acid, and this was the cause of the oxalate sediment. These cases may properly be called oxaluria. There is, as yet, no reason for looking upon them as a distinct anomaly of metabolism. Oswald¹ believes that increased oxalic acid excretion is associated with those diseases in which there is an increased breaking down of tissue, and that the source of the oxalic acid is the connective tissue. This coincides

Fig. 254.—Crystals of calcium oxalate: a, So-called envelopes; b and c, rarer forms (after Scheube).

¹ Oswald, *Lehrb. der chem. Pathologie*, Veit, Leipzig, 1907.

with the observation that one obtains an increased excretion in diabetes mellitus and gout, but in typhoid, pulmonary tuberculosis and pernicious anemia.

The formation of oxalate calculi will, of course, be favored by an acid condition. According to Fürbringer, calcium oxalate is in all probability a normal urinary constituent, held in solution in the urine by the acid sodium phosphate. If for any reason the acid reaction is reversed, that the acid phosphate becomes converted to a neutral salt, calcium oxalate becomes precipitated. Ordinarily, the double change from acid urate and acid phosphate mentioned in connection with the formation of urate sediments is the cause of the reduction of the acid reaction; and besides the urates, calcium oxalate precipitates. The separation of calcium oxalate usually takes place very slowly, and it therefore generally occurs as well-formed crystals (Fig. 254). They usually present a characteristic octahedral type (envelope); but other varieties also occur (see Fig. 254, note to Fig. 255), which cannot, however, be recognized immediately from their shape.

From the way in which calcium oxalate crystals separate, it is evident that they may occur in faintly acid, in neutral, and in faintly alkaline urine. Calcium oxalate crystals are characterized not only by their shape and insolubility in acetic acid, but by the fact that they are soluble in hydrochloric acid.

A tendency to the formation of oxalate calculi will be found in many cases where oxalate sediments occur in the urine.

The foregoing explanation of the separation of calcium oxalate crystals makes it evident that their appearance in the sediment does not justify the assumption of increased formation of oxalic acid. More than urate sediment necessarily implies increased uric acid. "Oxaluria" is often diagnosed without sufficient reasons. An increase in the elimination of oxalic acid can be determined only by a quantitative urinalysis.

SEDIMENTS OF THE EARTHY PHOSPHATES AND CARBONATES AND AMMONIUM URATE

They are usually light in color, because they are less inclined than the urates to absorb the urinary pigments, and because their separation does not depend so much upon the degree of concentration as upon the reaction of the urine.

1. Amorphous Earthy Phosphates and Carbonates.—The earthy phosphates and basic phosphates and carbonate of calcium and magnesium occur in the urine as granular and amorphous masses, and may be present in even the most alkaline urine, particularly if the alkalinity be due to a fixed alkali. These salts are also precipitated if the urine be artificially rendered acid, or if a faintly acid, neutral, or faintly alkaline urine be boiled, the combinations in which calcium and magnesium phosphate and carbonate are dissolved in the urine being changed to basic combinations by heating. Their precipitation produces a turbidity which, unlike the precipitation of protein from heating, is soluble in dilute acids. The carbonates are dissolved by dilute acids give off CO_2 , a peculiarity which distinguishes them from the phosphates.

A crystalline precipitate of calcium carbonate sometimes appears as a sandy powder mixed with the amorphous phosphate sediments. Microscopically, it consists of spheric or dumb-bell-shaped formations.

255), which dissolve in acetic acid with the evolution of gas, and so can be distinguished from similar formations of calcium oxalate. (See p. 673.)

2. Ammoniomagnesium Phosphate (Triple Phosphate) and Ammonium Urate.—These are combined with the amorphous phosphate and carbonate sediment if the alkaline reaction of the urine be entirely or partially due to the formation of ammonium carbonate within

Fig. 255.—Indistinct crystalline sediment (dumb-bell crystals) of calcium carbonate. Similar crystals are formed by calcium oxalate and calcium sulphate (after Funke).

Fig. 256.—a, Crystals of ammoniomagnesium phosphate (triple phosphate); b, crystals of ammonium urate (after Neubauer and Vogel).

Fig. 257.—Other forms of triple phosphate crystals (after Peyer).

the urinary passages from the urea, or, after voiding the urine, from bacterial fermentation. In such a condition triple phosphate will compose

the major part of the sediment. The prisms, the so-called "coffin-lids" (Fig. under the microscope. The ammonium companies the triple phosphate crystals precipitated in an alkaline urine. This with projecting spines, "star or thorn-ammonium urate dissolve in acetic acid with acid. Ammoniomagnesium phosphate crystals in acetic acid. Although both these crystals in ammoniacal urine, they also appear in urine if an ammoniacal fermentation has

3. Dicalcium phosphate (neutral phosphate) is a rather rare sediment, formed in urine as microscopic prismatic or wedge-shaped (Fig. 258). These crystals are soluble in frequently only indistinctly developed.

4. Crystalline Trimagnesium Phosphate has been observed in alkaline urine large, flat, striated or elongated rhombic plates with angles of 60° (normal magnesium phosphate).

THE SO-CALLED PHOS

The occurrence of phosphate sediments in *phosphaturia*, and a latent condition, in which the phosphate has been differentiated from that in which the urine sediment is mostly amorphous phosphates, some. The term *phosphaturia* may be used, but was not used by writers, who assumed that it was an anomaly. The increased output of phosphates or phosphoric acid is the excretion of a phosphate sediment, either always associated with a decreased acidity of the urine, or the urine may be actually alkaline. A *phosphaturia*, with the carbonates, is most often observed when, through the hydrochloric acid secreted by the stomach is definitely lost to the body. Other cases are seen in which the urine is excreted turbid, especially after meals (and a permanent condition of this kind is seen). The temporary excretion of phosphates after meals is explained by the fact that during the time of digestion the blood and urine become more alkaline, and the secretion of hydrochloric acid into the stomach may be explained by assuming that, owing to the loss of the acid is not absorbed and the alkali balance is disturbed. Other causes, which have been mentioned in connection with the excretion of the urine (see p. 556), favor the precipitation of the phosphate in the urine has undergone alkaline fermentation. The *phosphaturia* which is found in *phosphaturia* is a special condition. Some of these cases void a sediment which are independent of meals. The previously believed that this was a special distal phosphatic diathesis. It has been shown that the excretion of phosphoric acid, which was supposed to be a catabolism of nervous tissue. The excretion of phosphates, therefore, appear that, in the increased excretion of phosphates, decreases in acidity or even becomes alkaline. In some cases, instead of a normal daily excretion of about 0.7 gm., and the ratio of calcium to phosphoric acid is increased. An explanation of this puzzling form, which should not be given. It is uncertain whether it is an

¹ Deut. Arch. f. klin. Med., 1

(not of phosphoric acid, but of calcium), or whether it is due to a functional disturbance of the kidney; further, whether the nervous condition is a cause or a sequel, or whether they are both symptoms of a more deeply seated condition. As there are no signs of a destruction of calcareous tissue, one must assume that the intestine, which excretes the greater part of the calcium, fails in its function and more calcium than normal is absorbed.

Clinically, in all forms of phosphaturia, in consequence of the decreased acidity of the urine, the dissociation of the ammonium salts is increased, and ammonia may be detected by placing a strip of moistened red litmus-paper above the urine without there being alkaline fermentation or increased excretion of ammonia.

It may be pointed out that it is often difficult to make out a decreased acidity of the urine as a common cause of phosphaturia. The precipitated phosphates are neutral or basic salts and take out basic substances from the urine, so that the clear fluid may show no decrease in acidity. In order to demonstrate such a masked decreased acidity, it is necessary to bring the phosphates into solution by the addition of a known volume of normal hydrochloric acid, and perform the titration, subsequently subtracting the acidity due to the amount of acid added.

The author also mentions that traces of albumin often accompany a phosphaturia. The significance of this has not been made out. (See Phosphatic Albuminuria, p. 562.)

Incompletely differentiated from the above are the symptom-complexes described by Tessier as phosphatic diabetes¹ and the "phosphaturie terreuse des dyspeptiques" of A. Robin.²

OTHER INORGANIC SEDIMENTS OR TURBIDITIES (RARE)

Gypsum (calcium sulphate) occurs very rarely, and only in the sediment of strongly acid urine. Its crystals are represented in Fig. 259. (Compare Fig. 255.) They are insoluble in ammonia, alcohol, and acetic acid; slightly soluble in hydrochloric acid, nitric acid, and hot water. Their aqueous solutions may be precipitated

Fig. 258.—Crystals of dicalcium phosphate from amphoteric urine (alter Neubauer-Vogel and Ullmann-Hofmann).

with barium chlorid, and the resulting precipitate is insoluble in hydrochloric or nitric acid. Ammonium oxalate also removes them from their aqueous solutions, and the resulting precipitate is insoluble in acetic acid, but soluble in nitric and hydrochloric acids.

Cystin.—Cystin occurs in the urine only very rarely (so-called cystinuria).³ This is a peculiar metabolic anomaly which leads to the formation of cystin and diamins. It was thought to be due to some peculiar intestinal mycosis, because these substances are also found in the intestinal contents. More recent investigations have shown that it is probably caused by an incomplete catabolism of the protein

¹ Lyon Med., 1875, xix, 307.

² Bull. gén. d. therap., 1900.

³ See Stadthagen and Brieger, Berlin. klin. Woch., 1889, vol. xxvi, p. 344, and Udránsky and Baumann, Zeit. f. physiol. Chem., 1890. The more recent literature will be found in an article by Blum, Semaine médicale, 1906, No. 47.

molecule. According to this view, both cystin and the diamins are normal products of intermediary protein metabolism, and their excretion in the urine is due to a failure on the part of the liver to catabolize them further. Cystin usually separates from an acid urine within the urinary passages in characteristic hexagonal, plate-like, colorless crystals (Fig. 260) (cause of cystin calculi).

Uric acid also separates in similar crystals, although quite exceptionally; hence cystin and uric acid may be confounded. The crystals of cystin are, however, perfectly colorless. To differentiate doubtful crystals chemically, ammonium

Fig. 259.—Crystals of gypsum (after Neubauer and Vogel).

hydroxid is added to the sediment. Cystin will be dissolved. The filtrate is then acidulated with acetic acid or, better still (Salkowski, Drechsel), allowed to stand exposed to the air for some time until the ammonia has escaped. Cystin will then be again precipitated in hexagonal disks. Uric acid is only very slightly soluble in ammonia, and also differs from cystin in being only slightly soluble in hydrochloric acid.

Tyrosin and Leucin.—Tyrosin very rarely appears as a sediment. It is recognized by its characteristic crystals. (Compare p. 605 and Fig. 240.)

Fig. 260.—Crystals of cystin (after Neubauer and Vogel).

Fig. 261.—a, Xanthin crystals; b, crystals from the solution of xanthin in hydrochloric acid (after Neubauer and Vogel).

Leucin is a still rarer sediment than tyrosin, and is then always associated with the latter. (Compare p. 605.)

Xanthin, although a normal urinary constituent, is very rarely observed as a sediment, and then under entirely unknown conditions. It forms whetstone-shaped crystals, which are differentiated from those of uric acid by being readily soluble in ammonia. Further, if xanthin crystals are evaporated with moderately concentrated nitric acid over a water-bath, they leave a yellowish-white residue, which turns to an intense yellow after careful heating over a small flame; then the addition of potassium hydroxid will change the color to a yellowish red, which

will become more deeply colored when freshly heated, and which will finally turn to a violet red when the potassium hydroxid is evaporated (Strecker). This test must not be confused with the murexid reaction (p. 673).

Cholesterin.—Cholesterin crystals have been found occasionally, and sometimes in considerable quantity (cholesterinuria), in the urine in diseases of the urinary passages (inflammation of the bladder, pyelitis, echinococci, chyluria, and nephritis). This occurrence is, however, extremely rare.¹ Cholesterin is supposed to be derived from the epithelium (Fig. 278, b).

Hematoidin Crystals (*Bilirubin*, compare Fig. 278, d²).—Hematoidin crystals occur, although very rarely, in the urine of hemorrhagic nephritis. Bilirubin crystals, on the contrary, are not infrequently precipitated in sediment of markedly icteric urine when cool, particularly if it be strongly acid or artificially acidulated. They can be easily recognized by their yellowish-red color, by their solubility in alkalis and chloroform, and by their reaction to Gmelin's test (p. 575 et seq.), under the microscope.

Indigo.—If the indican be increased in the urine, indigo may separate as pointed or rhombic crystals. These may either be found in the sediment or form a scum on the surface. They dissolve readily with a blue color in chloroform (pp. 554 and 579).

Melanin.—Melanin separates in rare cases as fine amorphous granules. It usually remains, however, in solution (p. 582).

Hemoglobin.—This may be precipitated while hemoglobin is still in solution, as a sediment of amorphous cakes or cylinders in hemoglobinuria. (Compare pp. 554 and 572.)

Fat.—A large amount of fat in the urine almost always signifies *chyluria* (lipuria). The urine is then albuminous, of a milk-white to a cloudy-yellow appearance, sometimes even slightly blood-tinged, neutral or faintly acid, forms a cream-like layer, and often contains small coagula. The latter may form within the body as well as after the urine is voided. (Fibrin and Fibrinogen Contained in the Urine, see p. 568.) A microscopic examination shows that the fat is subdivided much more finely in the urine than in the milk. No distinct fat-drops can be seen, but extremely finely divided, almost invisible, fat-granules. These granules furnish the cloudiness and the cream-like layers. The other characteristics of this fatty admixture are the same as those that will be described later on. (See p. 911 in reference to the chylous fluids sometimes found in the serous cavities.) Chylous urine does not contain sugar, since this substance is not removed from the intestine by the lacteals, but by the veins. Chyluria is well known to be a tropic disease caused by a thread-worm, *Filaria sanguinis*, which inhabits the blood. The urine occasionally contains the embryos of the *filariae*. (See Fig. 272.)

The occurrence of tropic chyluria is due to the presence of adult *filariae* in the thoracic duct, producing a stasis of the chyle, which extends not only to the lymphatics of the intestines, but also to those of the urinary apparatus. In such cases chyle may become admixed with the urine by diapedesis or by rupture of those lymphatics which do not ordinarily contain chyle. In one case Havelburg succeeded in definitely proving that the escape of chyle into the urine took place in the bladder. The frequent simultaneous admixture of blood is to be explained, according to Scheube, partly by the coincident rupture of blood-vessels and varicose lymphatics, and partly by the disappearance of the tissue between the venous and lymphatic vessels, due to the lymph stasis, whereby the contents of the lymphatics become mixed with blood. A similar stasis of chyle, produced in different ways in individual cases, may probably be the cause of the rare chyluria observed in this climate. These cases may be explained by the observation of Porf,³ which, by reason of pressure from a tuberculous gland on the thoracic duct, caused the appearance of chyle in the pelves of both kidneys, due to the stasis of the fluid.

If the amount of fat contained in the blood be abnormal (lipemia), the urine also contains an abnormal amount (bone fractures, fat-embolism, diabetes mellitus, alcoholism, and acute phosphorus-poisoning). (See Examination of the Blood.)

A small amount of fat is also found in the urine in Bright's disease when the kidney elements (casts and epithelium) are eliminated in a fatty degenerated condition. The fat is then ordinarily inclosed within cells or casts, but exceptionally it may appear as fat-drops floating upon the surface, as a result of the degeneration of the cells or casts. Crystalline needles of fat have in a few cases been

¹ Cf. Hirschlaff, Deut. Arch. f. klin. Med., vol. lxii, p. 531.

² Hematoidin and bilirubin are usually considered identical.

³ Zeit. f. klin. Med., 1906, lix, pp. 2-4.

found in the urine. Such crystals are sometimes formed within the body, sometimes only outside from the fluid fat (Fig. 278, a).

The examiner must, of course, be careful not to confound contamination from dirty vessels or catheter grease with *lipuria*.

If the macroscopic or microscopic appearance of the urine does not suffice for the demonstration of fat, then the urine should be extracted with ether. After evaporating the ether the physical characteristics of the fat are more easily recognized (grease spots), or an odor of acrolein (like smoking tallow candles) can be demonstrated if the residue be heated on a platinum foil, or, if the fat contain oleic acid, the addition of a 1 per cent. solution of osmic acid will turn the residue black.

According to Späth, *hippuric acid* has been observed in urine, in rare cases in the shape of prisms or needles. The factors governing its occurrence are not yet definitely known, although it seems to have been more frequently observed after the administration of salicylic acid.

MUCOUS SEDIMENTS

If the urine contain considerable nucleo-albumin (compare p. 571 et seq.), it will separate spontaneously as a sediment of mucus-like consistence. Such a sediment consists microscopically of a cloud of clotted, transparent, indistinct masses. The addition of acetic acid will make their contours more distinct. They sometimes inclose various morphologic elements, white blood-corpuscles, epithelium, crystals, etc. Epithelial elements and white blood-corpuscles are almost always found in mucous sediments, because the increased nucleo-albumin is the product of a catarrhal disintegration of the mucous membrane.

APPENDIX TO DISCUSSION OF INORGANIC SEDIMENTS. URINARY CALCULI

Many of the substances enumerated as inorganic sediments are, under certain conditions, eliminated in the urine in the shape of concretions or urinary calculi.

Only the most important points in recognizing the various forms of urinary calculi will be mentioned here. The earthy phosphatic calculi are distinguished by their friability. The commonest calculi, those of uric acid and urates (urate calculi), are far more firm. The hardest of all are the calculi of calcium oxalate (so-called oxalate calculi).

The rare cystin calculi are usually yellow, smooth, small, and soft as wax; the still rarer xanthin calculi are clearer, rather hard, and when rubbed, exhibit a wax-like polish. Calculi of cholesterin are also very rare and resemble the cystin concretions. The concrements, consisting of fat and of fatty soaps of the alkaline earths and designated as urosteoliths, are extremely rare; they are characterized by their light color, soft consistence, and hardness when dried. Mention should also be made of a single recorded instance of a calculus consisting of indigo, which was sufficiently characterized by its color. Urinary calculi frequently consist of different substances arranged in layers, each of which may be more or less distinctly recognized by the previously mentioned characteristics.

For qualitative analysis a finely powdered specimen of the stone is first heated upon platinum foil. If the specimen burns up entirely or nearly so, it is composed of uric acid, xanthin, or cystin. Cystin and xanthin dissolve in dilute hydrochloric acid; uric acid does not. Uric acid may also be recognized by the *murexid* test (p. 673). Xanthin can be distinguished from cystin, as shown on p. 678. To identify cystin, Salkowski digests the powder with ammonium hydroxid, filtered, and evaporates the filtrate in a watch-glass. Cystin crystallizes out in its characteristic hexagonal plates (Fig. 260). Cholesterin is characterized by its solubility in ether and by the beautiful rhombic plates which are formed by evaporating this ethereal solution.

If the powdered calculus does not burn up entirely upon the platinum foil, it must contain either lime or magnesia. If in such a case the powdered specimen completely dissolves in dilute hydrochloric acid, it contains no uric acid along with the alkaline earths. What dissolves must consist of phosphates, carbonates, or calcium oxalate. Carbonates can be recognized by the development of gas. Calcium oxalate can be recognized by the fact that (by acetic acid) it is precipitated gradually, as a flaky cloudiness, from the dilute HCl solution neutralized with clear ammonium hydroxid. If any residue remain after the treatment with dilute hydrochloric acid, it generally consists of uric acid, which can easily be identified by means of the *murexid* test (p. 673).

ORGANIC ADMIXTURES AND SEDIMENTS OF URINE

As to the method of isolating these, see p. 669 et seq., at which place will be found the necessary information in reference to the elimination of interfering sediments composed of urates, phosphates, or carbonates.

MACROSCOPIC IDENTIFICATION OF ORGANIZED URINARY SEDIMENTS

These sediments differ from non-organized in their insolubility on heating, or even after the addition of hydrochloric and acetic acids. They do not sediment as rapidly as the non-organized, so that a urine from a catarrh of the bladder, or one containing blood, may remain clouded for hours, while a urine containing urates or phosphates sediments rapidly. This is due to the low specific gravity of the former elements. Blood-corpuscles sediment most rapidly; bacteria often not at all. Further distinctions are given in Doune's test for pus, the detection of blood-coloring matters, the behavior of bacteria toward chemic reagents.

PRESERVATION OF THE ORGANIC SEDIMENT

If it be impossible to examine an organic sediment immediately after settling or after centrifuging, it may be preserved by washing several times with a normal salt solution and then kept in 1 per cent. osmic acid. The fat-drops of the cellular elements will be colored black if they contain any oleic acid. Instead of this procedure¹ the sediment, which has been washed with physiologic salt solution, may be hardened in a 1 : 20 sublimate solution for five minutes and then preserved in a 2 to 10 per cent. formalin solution. Formalin will destroy the red blood-corpuscles if they have not been previously hardened in the sublimate solution, hence the hardening by sublimate may be omitted if there are no red cells. May² calls attention to the fact that even in a case of this sort the urinary sediment must be first washed, otherwise considerable sediment of spheric crystals of di-formaldehydurea readily forms.

STAINING OF THE ORGANIC SEDIMENT

There is no perfectly satisfactory method for staining a urine sediment. Most pigments produce precipitates after being added to the urine, so that the sediment is disfigured by granular masses. Dry specimens are unsatisfactory, because urine with an organic sediment is always more or less albuminous, and dried protein stains strongly; hence the dry preparations are never neat. These disadvantages may be partially obviated, although in a rather cumbersome way, by washing the sediment repeatedly with normal salt solution, repeating the sedimentation, then drawing off the fluid repeatedly with a pipet, thus separating it from the urinary constituents which are held in solution, especially from albumin, and then finally

¹ Gumprecht, Centralbl. f. inn. Med., 1896, No. 30.

² Arch. f. klin. Med., vol. lxxviii, p. 425.

adding the staining pigment. A cover-glass preparation may then be made in the same manner as with sputum. (See pp. 710 and 715.) The sediment must not be washed for too long a time, however, or sufficient material will not be obtained for the cover-glass. The same rules apply to the staining of the dry preparation as obtain in the examination of the sputum. If the attempt to make a dry preparation be unsuccessful, the moist sediment may be best stained according to the method of T. Liebmann.¹ The urine is centrifuged, the supernatant fluid poured off, and the sediment treated with 2 to 4 drops of a solution of 2 gm. of methylene-blue (Merck) in 100 cc. of a 10 per cent. solution of formalin. The sediment and the staining solution are then well shaken in the centrifuge tube and allowed to stand for several minutes. The tube is then filled with water to remove the salts and the excess of stain, the solution is again centrifuged, and the sediment placed beneath the microscope. Hyaline casts are stained light-blue, waxy casts dark blue, nuclei and bacteria dark blue, and red blood-corpuscles grayish blue. This method may also be employed for specimens preserved with formol.

If it be desired to demonstrate the fatty elements, a good method of staining the urinary sediment is that of Cohn:² The dry slide is hardened in a 10 per cent. solution of formalin for about ten minutes, then washed with water, and placed for ten minutes in a concentrated solution of Sudan stain in 70 per cent. alcohol.³ Fat is stained red and the nuclei violet.

May⁴ suggests, in order to prevent the formation of insoluble deformaldehydurea, to wash the sediment before treating it with formaldehyd.

Posner recommends hardening the dry preparation with osmic acid. He proceeds as follows:⁵ Several crystals of osmic acid are placed in a wide-mouthed dark-glass bottle provided with an accurately ground-glass stopper. The moist, smeared glass-cover is now placed over the mouth of the open bottle, with the smeared side down. This is accomplished by making the clean side of the cover-glass adhere to a slide by means of a drop of water. The slide is then held in position by the dark-colored stopper, so that light is excluded. Fixation is completed in forty seconds. The cover-glass is then dried in the air, and stained without previous washing. Posner found that this treatment adapted the preparation for all the finer staining methods, and that it was also applicable for blood-preparations.

N. Iagié recommends the method which is given in the section on Puncture, and which is used for staining the cellular elements of an exudate. This method is successful in staining urinary sediments.

EPITHELIUM

Scattered epithelial cells may be found even in normal urine. The desquamation of epithelium is a normal physiologic process. If they are present in large numbers, however, they point to inflammatory and destructive changes of the urinary apparatus. The following kinds may be distinguished:

Renal Epithelium.—They are generally spheric or cubic, a little larger than white blood-corpuscles, often distinguishable from the latter only by their larger size and by their large single nucleus. The nucleus is readily seen, and looks like a bubble, especially when stained. (Compare p. 685.) They may show any degree of fatty degeneration, and may eventually become disintegrated to form a conglomeration of fat-drops. These cells are very uncommon in normal urine, but in some forms of nephritis are very plentiful (Fig. 262).

Epithelium of the Urinary Tract.—These present extremely varied forms. The cells of the upper layers are generally flat, round,

⁵ Berlin. klin. Woch., 1903, vol. xxxii.

or polygonal; those of the deeper layers are elongated and provided with processes. Fig. 263 illustrates a number of these cells. A considerable quantity of the epithelium of the urinary passages is thrown off in all inflammatory processes. It was formerly believed that all cells provided with prolongations always came from the pelvis of the kidney. Unfortunately for the differential diagnosis of pyelitis and cystitis, this old idea is not true. No absolute point of differentiation between epithelium of the pelvis of the kidney and that of the bladder has yet been found. Nevertheless, a very great predominance of caudate epithelium, as compared with the permanent variety, suggests pyelitis rather than cystitis. Fig. 264 represents the sediment taken directly from the pelvis of the kidney in a case of pyelitis.

Fig. 262.—Renal epithelium from nephritic urine: *a*, Polyhedral renal epithelium in nephritis of scarlet fever; *b* and *c*, different grades of fatty degeneration in renal epithelium in chronic nephritis ($\times 400$) (after Bizzozero).

Vaginal and preputial epithelia are typical large pavement cells. Their shape should be familiar, because their accidental occur-

rence in the urinary sediment may lead to the erroneous presumption of desquamative affections of the urinary tract. If a catheterized specimen be examined, no such mistake is possible.

PUS-CELLS

Pus-cells may also appear in the urine in all inflammatory processes of the urinary tract or kidneys or when an abscess breaks into the urinary tract. Their number may vary greatly. Sometimes they form the chief part of an abundant sediment, and sometimes they are only

found scattered. When the urinary tract is diseased, the amount of pus in the urine may be great, but in disease of the renal parenchyma proper, the pus-cells are usually very few. The origin of the pus-cells can be determined with some degree of certainty only when the presence of other morphologic elements (epithelium, casts) serves as an indicator.

Fig. 264.—Sediment from a case of pyelitis, taken directly from the pelvis of the kidney at the post-mortem examination.

The sudden appearance of a pus sediment in the urine suggests the rupture of an abscess into the urinary tract, provided that the other clinical signs correspond with this assumption. The occurrence of thread-like formations is very characteristic of a gonorrheal sediment (gonorrheal

Fig. 265.—Sediment in alkaline inflammation of the bladder: pus, epithelium, and triple phosphate crystals (after Peyer).

threads, compare p. 690). They consist of pus-cells glued together with mucus.

In females the pus sediment may come from the vagina. To exclude such a possibility, either the vagina must be thoroughly irrigated before the urine is voided, or the urine must be drawn with a catheter.

With alkaline fermentation a pus sediment is oftentimes converted into a ropy, gelatinous mass by the swelling of the pus-corpuscles. Purulent urinary sediments are often of a slimy consistence, even if the urine be not alkaline, because the urine in inflammatory affections usually contains nucleo-albumin.

The pus-corpuscles voided in the urine vary in their microscopic appearance, which depends partly upon the length of time since their escape from the blood-current, and partly upon the consistence of the urine, or upon the nature of the affection in question. Sometimes they are very cloudy and shrunken, so that the nuclei can be seen only after the addition of acetic acid (usually polynuclear or with nuclei irregularly crumbled); sometimes in an alkaline urine they are much swollen and glossy, and in this case also the nuclei are not easily seen. In faintly alkaline, neutral, or faintly acid urine, on the contrary, the pus-corpuscles are often well preserved and sometimes even show active ameboid movements, especially when the slide is slightly warmed. The most important point of differentiation between pus-corpuscles and

Fig. 266.—Sediment in acid inflammation of the bladder: pus, red blood-corpuscles, and epithelium (after Peyer).

epithelium, especially renal epithelium, is the shape of a number of the nuclei. In the pus-cells the nuclei are usually multiple or very irregularly shaped, never bubble-shaped. This can be best recognized in a stained specimen (p. 682). The size must also be considered. The pus-corpuscles are usually of a diameter of 7 to 10 μ , corresponding to the polynuclear leukocytes from which they arise, whereas the epithelium cells are usually much larger. Figs. 265 and 266 represent the purulent sediment of alkaline and acid inflammation of the bladder or of pyelitis.

Of course, pus-containing urine always contains protein in solution. It is a part of the quantitative estimation (see below) to decide whether the albuminuria, when pus is present, can be explained by the admixture of pus plasma only, or whether we must assume the simultaneous occurrence of a true renal albuminuria. In the latter case the amount of protein is much greater. According to Posner, 100,000 pus-corpuscles in a cubic centimeter correspond to about 1 per cent. of protein. Morphologic elements characteristic of true albuminuria (casts, renal epithelium) will, if present, decide this question. Filtration does not remove

the protein of pus plasma, although this erroneous view has so often been maintained.

Posner formerly suggested that the amount of pus present in the urine could be estimated by counting the number of pus-corpuscles in the centrifugalized twenty-four-hour amount of urine (analogous to counting the red blood-corpuscles) by means of the Thoma-Zeiss counting apparatus. This process is too complicated for practical purposes, so Posner, in a later communication,¹ announced another method of estimating the amount of pus mixed with the urine, or of the amount of sediment in general. The procedure is as follows: The transparency of the urine (the specimen must, of course, be taken from the mixed twenty-four-hour urine) is determined by placing a beaker with flat bottom upon a piece of paper with ordinary-sized print, and estimating the height in centimeters to which it is necessary to fill the beaker, so that in good daylight the print can no longer be read. The degree of transparency is indicated by the thickness of the layer in centimeters. Posner found that a transparency of $\frac{1}{2}$ to 1 cm. corresponded to 40,000 pus-corpuscles per centimeter, and a transparency of 6 cm. to about 1000 pus-corpuscles. Eight centimeters' thickness and above he assumed to indicate normal conditions. Such a quantitative estimation of the amount of pus present is important for estimating the effect of therapeutic interference in cystitis and pyelitis.

BLOOD

Red corpuscles are found in the urine in hemorrhagic inflammation and tumors of the urinary tract and of the kidneys, in traumatic hemorrhage, in calculi, in hemorrhage from congestion, and in hemorrhagic diathesis. The blood-corpuscles appear in the urine partly intact, and partly changed in various ways by the action of the urine. They are most frequently both swollen and minus their pigment, exhibiting only the pale, shadow-like stromata, sometimes as pale disks and sometimes as peculiar, almost invisible, circles. Often the blood-corpuscles break up into small masses of substance containing hemoglobin.

In determining the diagnostic significance of blood-cells in the urine, we meet with the same difficulty as in determining the significance of pus-corpuscles—the difficulty of being sure of their source. In this connection also we must determine whether the amount of protein present in the urine may be explained by the admixture of blood alone, or whether it depends upon renal albuminuria as well. In the latter case the hemorrhage probably comes from the kidneys. If casts with blood-corpuscles adherent or blood-casts also occur in the sediment, the source is certainly a renal hemorrhage. Hemorrhage which leads to the elimination of larger blood-coagula in the urine usually arises not in the kidney parenchyma, but in some part of the urinary tract lower down—either the pelvis of the kidney or the bladder. It should be remembered, however, that in cases of hemorrhage from the renal parenchyma due to nephritis, blood-clots of considerable size may sometimes be found in the urine. A characteristic shape of the coagulum may point to its source from the pelvis of the kidney or the ureter. A considerable amount of blood at the end of micturition probably indicates bladder hemorrhage.

¹ Deut. med. Woch., 1897, No. 40.

Gumprecht¹ claims that if most of the blood-corpuscles are fragments, i. e., disintegrated to small masses, the kidney is generally the seat of the blood-extravasation. In hemorrhage of the bladder, on the contrary, but a few fragmented blood-corpuscles will be found. As concentrated solutions of urea (as low as 8 per cent.) cause fragmentation of the red blood-corpuscles, Gumprecht maintained that the above-mentioned difference is due to the influence of the urea contained in the renal epithelium upon the extravasated blood. The amount of urea in the urine itself is said to be insufficient to produce the change. An objection to this supposition is that it is probable that the blood-corpuscles never come in contact with solutions of urea of the above-mentioned concentration in the kidney. In the opinion of the author, it is more likely that the fragmentation is caused mechanically by the contusion of the blood-corpuscles in the urinary tubules.

CASTS

Urinary casts are characteristic microscopic formations of cylindric form (Fig. 267), which originate in the kidney tubules. They are elimi-

Fig. 267.—Casts in nephritis: *a*, Epithelial; *b* and *b'*, granular; *c*, waxy; *d*, *d'*, hyaline; *e*, blood-cast; *f*, cast of white blood-corpuscles; *g*, hyaline cast with epithelium and white blood-corpuscles adherent; *h*, waxy cast with epithelium and red blood-corpuscles adherent (*h* and *b'*, after Bizzozero).

nated in the urine in nearly all cases of renal albuminuria, and infrequently even without albuminuria. Albuminuria may occur without

¹ Deut. Arch. f. klin. Med., 1894, vol. liii.

casts; but, generally speaking, elimination of casts and albuminuria go together. Casts occur most commonly in the various kinds of nephritis, but they may be present in the albuminuria of passive congestion as well as in other types of renal albuminuria. Nevertheless, casts may be absent in all these cases. If the renal albuminuria does not depend upon nephritis proper, this is much more apt to be the case. In nephritis the degree of albuminuria and the number of casts eliminated are usually quantitatively proportional one to the other. Exceptionally, however, and then only for a short time, casts may be absent even with a considerable amount of renal albuminuria. The occurrence of casts without albuminuria (a rare condition) has been observed in very chronic cases of nephritis, in contracted kidney, and in jaundice.

The principal varieties of casts are the following (Fig. 267):

- (1) Epithelial casts (*a*), composed of epithelium.
- (2) Granular casts (*b* and *c*), granules partly soluble in acetic acid and partly consisting of fat.
- (3) Waxy casts (*c*), strongly refractive, sharply outlined, often of a slightly yellow color.
- (4) Hyalin casts (*d*), pale, indistinctly outlined, seen readily only with a slanting light.
- (5) Blood-casts (*e*), composed of red blood-corpuscles or casts with red cells adherent, yellowish red to brownish, sometimes decolorized.
- (6) Casts of white blood-corpuscles (*f*).

Besides these there are many intervening varieties—*e. g.*, hyalin or waxy casts with red or white blood-corpuscles or epithelium adherent (*g* and *h*).

Fatty casts are casts which contain fat in such large quantities that the ground-substance of the cast is entirely obscured. Casts may be composed of pus or of bacteria. Such occur in infections, pyelonephritis, and in the kidney of pyemia. Other casts may become filled with bacteria in infectious conditions of the urinary apparatus, in the kidney itself or in the urinary tract, and even outside the body in urine containing bacteria. In uric-acid infarct of the new-born so-called uric acid casts are found, consisting of spheres of sodium urate. Casts of any variety may become incrustated with urates in a concentrated urine after standing; they then present a peculiar dark granular appearance. They are differentiated from true granular casts by their uneven margins. The urate granulation disappears as soon as the urine is warmed or rendered alkaline.

The length and thickness of casts vary greatly. It is impossible to draw any conclusions as to the source of the casts in the kidney tubules from their diameter, because the diameters of the renal tubules are changed in pathologic affections of the kidney parenchyma. Sometimes the casts present peculiar screw-like twists, but such a peculiarity does not mean that they originate in the convoluted tubules. We require a microscope to see casts properly unless they are very thick and long.

The epithelial casts evidently consist of desquamated epithelial cells which are eliminated adhering to each other. These casts sometimes possess a lumen, and are then spoken of as epithelial "tubules." In a similar way extravasated red corpuscles form the so-called blood-casts, and the leukocytes the white-corpuscle casts. Any of these conglomerations of cellular elements may be so tightly compressed or disintegrated that the cell borders become more and more obliterated. Such changes, the nature of which we do not well understand, may take place in the kidney tubules themselves or in the urine after voiding.

All grades of intermediate forms which still have the stamp of their origin merge without any sharp division into granular and waxy casts in which no nuclei or cell-walls are to be distinguished. The existence of such transitional forms makes it probable that the granular and waxy casts originate as cell conglomerations. In these the epithelium and leukocytes appear to play the chief part, the red corpuscles a much smaller one. This view as to the genesis of the waxy and granular casts is supported by many investigations upon the diseased kidney itself. Formerly the casts which contained no cells, the granular and waxy as well as the hyalin, were considered to be coagulated. Whether this genesis can still be considered, in view of what has already been mentioned, has not yet been certainly decided, but it is not improbable that the hyaline casts are really formed by exudation. It is as yet still unknown by what process the hemoglobin which separates from the blood in solution in hemoglobinuria assumes in the kidney tubules the form of solid casts—the so-called hemoglobin casts. It can, however, be easily conceived that these do not consist solely of hemoglobin, but only represent hyalin and waxy casts infiltrated with hemoglobin.

We have but little accurate knowledge of the chemical nature of casts. Once in a while some cast (especially a waxy one) will give an amyloid reaction, *i. e.*, stain red with gentian violet and brown with iodine, although such a reaction does not indicate any amyloid degeneration of the kidney itself, for, as a matter of fact, in amyloid disease such a reaction of the casts is hardly ever observed.

The importance of finding casts in the urine is due to the fact that they always indicate some pathologic condition in the kidney, and, if accompanied by albuminuria, make it practically certain that the kidney itself is involved. But the change in the kidney need by no means be of a severe anatomic nature. Even slight disorders which produce but a temporary albuminuria may be accompanied by casts, although in small numbers.

For the distinction between nephritic albuminuria, on the one hand, and febrile or congestive albuminuria, on the other, we may lay down the rule that, if casts do occur in the latter, this is the exception. They are almost always merely hyalin. But both the febrile and congestive albuminuria may change to a nephritis without any very sharp borderline.

Little can be claimed for the diagnostic importance of the different varieties of casts. Granular and waxy casts (as opposed to hyalin and epithelial) were formerly supposed to indicate a chronic process; but the idea was wrong. Any and all varieties of casts may be found in every type of nephritis, and even an amyloid kidney does not produce any distinctive type casts (see above). Generally speaking, granular and waxy casts probably owe their peculiar characteristics to the fact that they have remained in the kidney tubules for some time. But that does not necessarily mean a case of chronic nephritis. As a matter of fact, it would probably mean acute nephritis or the acute exacerbations of chronic nephritis, as in such cases the casts remain especially long in the kidneys because the excretion of urine is most interfered with.

MUCOUS CASTS (Cylindroids)

These are peculiar formations which an inexperienced observer may mistake for true casts. They are, however, less distinctly outlined, shaped more irregu-

larly, sometimes flat and tape-like, of smaller diameter, and frequently branching. They probably consist of mucus, *i. e.*, of the undissolved portion of nucleo-

Fig. 268.—Cylindroids (after Peyer).

protein contained in the urine. They are, generally speaking, pale and hyaline, but may be covered with urates, and then appear granular. (Compare p. 688.) They are of no especial diagnostic importance.

TESTICLE CASTS

In spermatorrhea certain formations are sometimes found in the urine which by themselves can hardly be distinguished from hyalin casts. The chemically normal condition of the urine, and the fact that this type of cast appears only in that portion of the urine leaving the urethra first, and is usually accompanied by spermatozoa, will generally suffice to differentiate them from true renal casts.

GONORRHEAL THREADS (*Shreds*)

In the late stages of acute gonorrhea, when the secretion becomes more of a mucous consistence, and in chronic gonorrhea, even when it gives rise to no other distinct symptoms, peculiar thread-like formations are found floating in the urine. They are up to 1 cm. in length, visible to the naked eye, generally pointed at the end, and of a yellowish to whitish color. Under the microscope we can see that they have a mucoid ground-substance, probably consisting of nucleo-albumin, in which pus-corpuscles and epithelium are embedded.¹ They are probably caused by accumulation of secretion in the longitudinal folds of the urethra, whence they are torn away by the stream of urine.

SPERMATOOA

Spermatozoa occur in the urine after coitus, nocturnal emissions, and onanism, in spermatorrhea, and after epileptic and other convulsive attacks.

FRAGMENTS OF NEW-GROWTHS AND ELASTIC FIBERS

We may find in the sediment bits of tissue which have been separated from papillomata and carcinomata of the urinary tract or, more especially, of the bladder. Similar bits may be caught in the catheter when irrigating the bladder. If such fragments are large enough to be sectioned and stained, the microscope will quickly determine their nature.

¹ Plate to be found in Peyer, *Atlas der Mikroskopie am Krankenbette*, 1887, *Plates* 62 and 63.

The demonstration of elastic fibers is sometimes quite important in the diagnosis of ulcerative processes of the urinary tract (Fig. 277). (See Examination of the Sputum.) The urine is first acidulated to prevent the formation of a phosphate precipitate, and then centrifugalized or allowed to settle. The liquid is then poured off from the sediment, and the latter gently heated with an equal quantity of diluted (10 per cent.) potassium hydroxid. This will destroy most of the morphologic constituents except the elastic fibers. The mixture is then diluted with water and centrifugalized again. If the urine contains a great number of elastic fibers, they may be recognized microscopically without further preparation. Elastic fibers must not be confused with vegetable fibers, which may gain access to the urine from the walls of a dirty vessel. The differentiation is discussed at p. 705—Examination of the Sputum.

MICRO-ORGANISMS

Urine which has been allowed to stand soon furnishes a very favorable medium for the growth of all kinds of bacteria, particularly if the surrounding temperature be raised. The development of these organisms will decompose the urine in various ways. The chemical changes which take place in the urine may lead to the decomposition of any organized admixture and also to deception as to its composition. It is, therefore, important to preserve the urine in a cool place, and to undertake the qualitative examination as quickly as possible after voiding. For this purpose a twenty-four-hour specimen is not necessary. The decomposition of the urine may be checked by adding chemically indifferent antiseptic substances, *e. g.*, several cubic centimeters of coarsely powdered camphor or one-fifth its volume of chloroform water, or the same amount of 0.1 per cent. solution of thymol. For the same reason urine glasses must be kept as aseptic as possible. This is best accomplished by washing them with water and then with a 0.1 per cent. sublimate solution or a 2 per cent. warm soda solution every time after they have been emptied, and then keeping them covered, so that they are not contaminated by the bacteria in the dust of the air.

As we have seen, bacteria are very frequently found in the urine. The microscope will quickly settle the question of their presence in the sediment. A diffuse contamination by bacteria alone may be responsible for a very pronounced turbidity. Such a cloudiness may be distinguished from one caused by unorganized material, as it is affected neither by heat nor by the addition of acids or alkalis. It differs from sediment composed of pus, epithelial cells, or casts in that the latter sediment (1) quickly settles and so clears the upper layers of urine, and (2) is practically always associated with the presence of protein. Shaking a urine extensively contaminated with bacteria often produces a peculiar opalescent, wave-like movement of the cloudiness. Also the opalescent film which appears upon the surface of a urine which has been kept for some time usually consists of bacteria.

The demonstration of bacteria in the urine is diagnostically important only when they occur in freshly voided urine or in a specimen obtained by catheterization. Then they consist either of great numbers of saprophytic bacteria, which are readily seen under the microscope without staining, and which produce abnormal decomposition of the urine within the urinary tract when the latter is diseased (bacteria of

ammoniacal fermentation and bacteriuria), or else of true pathogenic bacteria, which can be recognized microscopically or cultivated upon appropriate media. The latter are found partly in local diseases of the urinary tract, as in certain cases of cystitis and especially in types of acute nephritis, and partly in general infections. They include such organisms as colon bacilli and staphylococci (Fig. 285), streptococci (Fig. 284), gonococci (Fig. 270), pneumococci (Fig. 281), typhoid bacilli, and tubercle bacilli (Fig. 280). In general infections in which bacteria (staphylococci, streptococci, pneumococci) are eliminated in the urine, it is still debatable whether the kidneys and urinary passages are unaffected or whether such elimination is always combined with a lesion of these organs. The microscopic demonstration of these bacteria is really far more important than the culture method of demonstration, because the former excludes the source of error of any incidental contamination, and because it gives more accurate information than the latter as to the quantitative importance of individual species in mixed infections. With a culture it may happen that bacteria of little or no pathologic importance develop inordinately.

The microscopic examination is performed just as with dry-sputum examinations, *i. e.*, dry preparations are prepared by spreading the sediment on cover-glasses (pp. 710 and 715 et seq.). If a specimen of urine is swarming with bacteria, a drop of the urine can be dried and examined like an ordinary dry preparation. If, on the contrary, the specimen of urine contain but few bacteria, it is better to examine a freshly and cleanly prepared sediment obtained by means of the centrifuge. Bacterial suspensions are so difficult to centrifugalize that if other morphologic elements are wanting, the examination will be simplified by first diluting the urine with alcohol. If the urine contain protein or albumoses, the precipitate which results from the addition of the alcohol aids in isolating the bacteria by helping to carry them down in centrifugalizing. Of course, such a precipitate should be merely flaky, otherwise it would interfere with making a good dry preparation. Should the alcohol precipitate large flakes, the urine must first be diluted. Dry preparations are prepared by spreading the sediment thinly upon a cover-glass (just as in sputum) and fixing over a flame. Fixation is, of course, sometimes difficult, because urea is hygroscopic. Hence it is often necessary first to wash the sediment several times with distilled water, centrifugalizing after each washing, or, if necessary, heating for a longer time over the flame, so as to convert the urea into ammonium carbonate. Staining can be accomplished exactly as with sputum preparations (pp. 710 et seq. and 715 et seq.). The bacteria may also be stained by the previously described method of Liebmman. (See p. 682.)

For cultures we must naturally employ perfectly fresh urine, withdrawn by means of a sterilized catheter into sterilized vessels after careful disinfection of the urinary opening. The first urine drawn in this manner must be thrown away, since it may contain bacteria which have been scraped from the walls of the urethra by the eye of the catheter. Even after observing this precaution the urine may become contaminated so that positive conclusions should not be drawn unless there are a large number of colonies.

The demonstration of *tubercle bacilli* in the urine is important for the diagnosis of tuberculosis of the urinary tract (Fig. 280). Dry prepa-

rations of the sediment are employed in the same way as with the examination of sputum (p. 710). In difficult cases the search for the tubercle bacilli may be facilitated by treating the sediment with sodium hydroxid (see p. 714), or tuberculosis may be proved to be present by inoculation experiments upon guinea-pigs. (See p. 714.) A difficulty in such a method is that other pathologic bacteria which occur in the urine

Fig. 269.—Smegma bacilli (\times about 800) (after Fränkel).

Fig. 270.—Gonococcus (\times about 800) (after Fränkel)

may multiply and kill the animal before the tuberculosis can develop. By washing the sediment before inoculation, the danger of such infection is lessened by the removal of toxic urinary substances. The reader should refer to p. 714 and to bacteriologic text-books for the details of performing an inoculation and for the conditions found in the inoculated animals.

Fig. 271.—Echinococcus elements: 1, Free scolices: a, rostellum projected; b, rostellum withdrawn; 2, hooklets; 3, membrane (\times cross-section) (after Heller).

The so-called *smegma bacillus* (Fig. 269 et seq.) has been so frequently confused with tubercle bacilli as often to lead to an erroneous diagnosis of urogenital tuberculosis. The smegma bacillus, as described by Alvarez and Tavel, occurs very frequently in the preputial fold of the male and in the folds above the female clitoris. In the specific staining for tubercle bacilli they also are stained (p. 712). From their location they can easily contaminate the urine and multiply in it outside of the body (?). These parts should, therefore, be washed very carefully before the urine is passed or before catheterization.¹

¹ Runge and Trautenroth have shown that the urine obtained by catheterization after carefully cleansing the external orificium urethrae is always free from smegma
